It is based essentially on the simple fact that fibrinous induration is to be regarded as the natural curative process in tuberculous lesions. The power of the chloride of zinc to excite such sclerotic processes, when administered in sufficiently small quantity to avoid its more powerful escharotic action, suggested its use in the disease in question. Its action in experimental tuberculosis is thus described by M. Lannelongue and M. Achard: The anatomical elements of the tissues which it penetrates are destroyed and an enormous proliferation of embryonic cells occurs, not only at the site of the injection but for some distance around it, with infiltration of the tuberculous tissues with migratory cells to the fullest extent. M. Lannelongue suggests that the latter may destroy the bacilli through the exercise of their phagocytic function. The morbid tissue destroyed by the chloride of zinc is slowly absorbed and disappears; the embryonic cells, on the contrary, organize with great rapidity and form firm fibrous tissue, which exists in appreciable quantity as early as the day following the injection.

Twenty-two patients were subjected to this treatment by M. Lannelongue. The list embraces two cases of pulmonary tuberculosis and twenty of suppurating and non-suppurating tuberculous disease of joints and glands. Excellent results are alleged to have been obtained in a majority of the latter. An opportunity was afforded, in a case of more or less fused tuberculous glands, for comparing histologically glands which had been injected and those which had been left without treatment. Excision showed caseous material surrounded by a zone of tuberculous tissue within a fibrous sheath in each; in the injected glands, however, there was a large amount of dense fibrous tissue, and there was firm adhesion to the investing membrane.

A report of the results in the pulmonary cases was reserved until a longer period had elapsed.

While recognizing the possible utility of this method of treatment in tuberculous joint and gland disease, either as a remedial measure or as an adjunct to surgical procedures, and suggesting the desirability of more extended investigations in this direction, its application in pulmonary tuberculosis, in my judgment, should be regarded with the greatest reserve. Aside from the difficulty of introducing intrapulmonary injections in any exact way at the site of the lesion, the extent and complexity of the morbid conditions usually present would seem to preclude the possibility of its usefulness as a method of treatment.

The technique of the method employed by M. Lannelongue is to inject two drops of a ten-per-cent. solution in a number of places around the periphery of the diseased part in cases of tuberculous joints, bones, and glands. Suppurating glands are thoroughly irrigated with sterilized water and the injections made under rigid antiseptic precautions. In cases of pulmonary tuberculosis a solution of one in forty is used for the injections.

**THE TREATMENT OF TUBERCULOSIS WITH CREASOTE, GUAIACOL, AND CARBONATE OF GUAIACOL.**—The literature of the treatment of phthisis pulmonalis with creasote, both by internal administration and by inhalation, is sufficiently familiar to those interested in the subject to warrant the briefest reference to it.

Discovered by von Reichenbach in 1830, it quickly secured a reputation in Germany, France, and England as a remedial agent in pulmonary diseases. It, however, gradually fell into disuse, and was only rehabilitated in favor in 1877 through the admirable clinical papers of Bouchard and Gimbert on its beneficial effects in consumption (35). Influenced by their statements, Beverley Robinson instituted its systematic use in his hospital and private practice in this city as early as 1878, and valuable papers by him have appeared from time to time since on this subject. In Germany, a series of publications by Sommerbrodt, Fraentzel, von Brunn, Guttmann, and others, confirmatory of the results obtained by Bouchard and Gimbert, appeared in 1887 and 1888. The literature of the subject at the present time is very voluminous, and it may be said to be exceptionally favorable to the value of creasote in the treatment of pulmonary phthisis. Varied opinions are held in regard to its mode of action, its most efficient dosage, and the best method of administration. The determination of these several points is of scientific interest, as well as of practical import.

The efficacy of creasote in hindering or arresting fermentative processes in the digestive tract, so frequently present in phthisical patients, and thereby promoting appetite, digestion, and nutrition, is very generally admitted. Its ability to favorably affect appetite, and to increase the digestive secretions when given by the mouth, by locally stimulating the gastric and intestinal nerve filaments, is also very probable. Through the promotion of a better nutrition, the beneficial effects alleged for creasote in stimulating the resolution and absorption of the secondary inflammatory exudations in tuberculous lungs may be explained. By its local action, antiseptic and stimulating, especially when given in the form of inhalations, a favorable influence upon

the simple catarrhal processes so commonly present is conceivable and probable.

In turning our attention to any *specific* action which creasote may exercise upon the pathogenic cause of tuberculosis and its specific lesions, the results of experimental investigations properly should be considered.

Guttman (36), as the result of test-tube experiments which, he maintained, demonstrated the power of creasote, in solutions of 1 to 4,000, to greatly inhibit the growth of the tubercle bacilli, and, in solutions of 1 to 2,000, to completely devitalize them, was led to believe that a similar specific action could be effected in the human body by the administration of sufficiently large doses of the drug. One gramme of creasote, according to his calculations, present in the circulation, would suffice for this purpose. The experimental investigations very kindly undertaken for me by Dr. John Ely, in the pathological laboratory of the College of Physicians and Surgeons, which will be given in detail later, confirm the correctness of Guttman's observations on the germicidal power of creasote.

Granting, therefore, the germicidal action of creasote *outside* of the human body, and also the possibility of administering it, without injurious effects, in daily doses larger than those demanded by Guttman's hypothesis, a seemingly fatal objection to the theory of the exercise of a germicidal action *in* the economy is found in very recent investigations, which indicate that creasote enters at once in the blood into chemical combinations with certain contained albuminoids—combinations which are without specific germicidal influence. Moreover, it has been wisely said that "man is not a test-tube," and no fact appears to be more clearly proved than that the germicidal action of a drug outside of the body affords little basis for correct conclusions of its therapeutic value. Experiments on animals are necessary to determine this point.

In pursuance of this idea, numerous investigators have attempted to test the antibacillary power, as well as other effects, of creasote in tuberculosis, by the treatment of animals with large doses of this drug both before and after the production of experimental tuberculous disease.

I shall refer only to the very interesting experiments of Trudeau (37) and Cornet (38).

*Trudeau's Experiments.*—Four rabbits were inoculated in the anterior chamber of the eye and in the right chest with a similar amount of pure cultures of tubercle bacilli suspended in water. Two of the rabbits were kept as "controls." Two were treated every other day with subcutaneous injections of 5 c. c. of a ten-per-cent. solution of pure creasote in almond oil. The course of the eye tuberculosis in the test animals was daily compared with that in the "controls," and was seen to be entirely uninfluenced by the treatment. Tubercles became visible in the iris from the twelfth to the thirteenth day in both sets of animals. Iritis, cloudiness of the cornea, and general secondary inflammatory changes were noted in all the rabbits from the eighteenth to the twenty-first day, and the sight was soon lost. All were killed two months after inoculation, and the lungs of both the test and the control animals presented the lesions of advanced tuberculosis.

*Cornet's Experiments* were as follows: Seven strong guinea-pigs were treated with creasote, introduced into the stomach by

means of a tube, in doses equivalent, for the body weight of a man, to rather more than two grammes daily for a period varying from one to two months. At the expiration of this interval they, with four control animals, were either inoculated with or were compelled to inhale finely atomized pure cultures of tubercle bacilli, the creasote being continued in the test animals. A single test guinea-pig died of pneumonia ten days after inoculation. The remaining six died, respectively, 30, 32, 33, 43, 77, and 84 days after infection. Two of the control animals were killed on the 32d and 43d day after infection; the two remaining died on the 61st and 84th day after inoculation. All the animals, both test and control, presented the characteristic lesions of tuberculosis, and very little, if any, appreciable difference in the appearance, the degree, or the distribution of these could be detected in the two sets.

Experimental investigations therefore show in the most positive manner that creasote, administered even in heroic doses, is incapable either of preventing the development of experimental tuberculosis or of arresting its progress.

The theory of Bouchard, Gimbert, Jaccoud, and others, that creasote promotes connective-tissue growth, by means of which recovery in tuberculous disease is favored, also is not borne out by experimental studies in animals.

The explanation of any favorable influence of creasote on sclerotic processes which *clinical* observations may indicate, should seemingly be sought in the improved nutrition which obtains through its use rather than by the exercise of any specific action.

Guaiacol, obtained by the fractional distillation of beech-tar creasote, and constituting from sixty to ninety per cent. of the latter, was suggested by Sahli (39), as early as 1887, as a substitute for creasote in the treatment of tuberculous disease. It represents the active principle of creasote and may be substituted appropriately for it. As prepared in the various laboratories it probably is not freed from all impurities. Owing to this fact, very lately Seifert and Hoelscher (40) have proposed the use of the carbonate of guaiacol. Carbonate of guaiacol possesses the advantages over creasote and guaiacol of being a simple, definite, crystalline substance, which can be obtained chemically pure. It is a neutral salt and is tasteless as well as odorless. It does not produce digestive disturbances, it is indifferent to the gastric secretion, and decomposes in the intestine into guaiacol and carbonic acid. Many of the above-mentioned characteristics of this salt have been demonstrated in its use in St. Luke's Hospital.

Seifert and Hoelscher, as the result of experimental studies with guaiacol carbonate, have advanced a new and interesting theory of the mode of action of the creasote preparations in tuberculous disease. The basis of their theory apparently rests on the fact that experiments on dogs show that creasote and guaiacol do not circulate in a free state in the blood, and that they are eliminated by the kidneys in the form of the salts of ethylsulphuric acid (*Aetherschwefelsäure*). They argue that during absorption the active principle of creasote allies itself with the albuminoids in the blood, and specifically through the agency of the sulphur contained in the albumin molecule. The blood of tuberculous patients contains, in addition to normal albumin, other albuminoid substances arising from the disease

process—*e. g.*, the products of the tubercle bacilli. These substances constitute unstable combinations, prone to cause or undergo chemical processes which act poisonously. The toxic albuminoids engendered by the disease are chiefly responsible for the fever, night sweats, etc. The guaiacol, by allying itself with them, renders them stable and therefore non-toxic. The chemical combinations effected by the guaiacol are without germicidal influence, and the favorable results obtained through the use of the creasote preparations in tuberculous disease, therefore, should be regarded as due in a large measure to their influence in assisting in the elimination of the toxic products of the specific disease process.

Seifert and Hoelscher's theory in no respect militates against other favorable influences which have been ascribed to the creasote preparations, such as the probable direct stimulation of appetite and thereby improved nutrition, etc.

The observations thus far made in St. Luke's Hospital in the use of guaiacol carbonate lead me to believe that it may be substituted very favorably for both creasote and guaiacol.

*Investigations in St. Luke's Hospital with Modified Tuberculin, Creasote, Guaiacol, and Guaiacol Carbonate.*—During the past winter sixty-five cases of pulmonary tuberculosis have been under my care continuously in the wards of St. Luke's Hospital. Many of these were cases of very advanced disease, without the possibility of recovery, and the treatment consisted merely in attempts to ameliorate the most distressing symptoms. Nineteen of the remaining cases were selected for treatment, respectively, with Hunter's modification of Koch's tuberculin, with subcutaneous injections of guaiacol, and with creasote by the mouth. It was my desire not so much to test the comparative merits of different methods of treatment as to corroborate or otherwise Cheyne's and Hunter's observations and to determine both the practicability of employing a very large daily dosage of creasote and any advantages this method might possess over its use in smaller quantities.

Seven cases of well-marked tuberculosis are embraced in the group treated with Hunter's modified tuberculin. The details of the histories of these patients and the results of treatment are given in a tabulated form for convenience of study. It will be seen that three cases have been under treatment for three months, the remainder for nearly two months. Physical examination in two of the former cases indicates no appreciable change in the pulmonary lesions during treatment. In the third case the improvement in the signs of disease and in all other respects has been most marked. Physical examination indicates not only the dryness of the cavity, but also its very evident contraction, as well as a diminution in the degree of the contiguous disease process.

In the four remaining cases, there has been no improvement in one; in one, improvement has been marked; in one, it has been distinct, though less marked; and in one, *an arrest of the disease*, at least temporarily, has occurred. It will be observed, in a study of the tabulated report, that by improvement is meant a marked diminution in the physical signs of disease. Case VII is certainly an example of arrested phthisis. This is of such rare occurrence

in pulmonary tuberculosis of this degree, under conditions which prevail in large city hospitals, as to be particularly noteworthy. A very distinct impression has been made on my mind in observing from day to day the cases treated with modified tuberculin, that its stimulation of the nutritive processes is not so marked as its effect upon the specific lesions. Creasote, on the other hand, has seemed to possess the former quality in a greater degree.

To meet possible criticism, all these cases have received no other treatment than tuberculin, beyond the administration of cod-liver oil and, from time to time, various ferruginous preparations.

The exact mode of preparation of the modifications used is given in a note. The rules of dosage were to give 0.002 gramme for the initial inoculation, and to increase by 0.002 gramme daily. The rule also was made *not* to increase the dose if any elevation of temperature followed inoculation.

With the modifications *B* and *CB*, appreciable reactions did not occur in these cases. In a single case not reported in the following table, treated with *CB*, a rise of temperature followed an inoculation of 0.008 gramme, and an acute catarrhal process was developed at the apex of one lung. At the expiration of the tenth day defervescence occurred and no further ill effect has followed.

For this reason, modification *B* has been used in all other cases but one. Trudeau has also adopted, I believe, modification *B* as the preferable one.

Through the absence of all reaction and discomfort attending the use of *B*, all patients treated with it have been able to be continuously about the wards and out of doors.

Only the usual very inexact method for determining the number of bacilli in the sputum was used. Repeated examinations were made, and they were found in all.

The number of cases treated with modified tuberculin, while much too small to permit the expression of a positive opinion of its power to exercise a specific remedial action, is large enough to indicate in the strongest manner the desirability of continued investigations of its *apparently specifically beneficial effects*.

*Method of Preparation of Hunter's Modifications.*—"Modification *B*: 1 c. c. of tuberculin, 5 c. c. distilled water, saturation with preferably large crystals of ammonium sulphate for twenty-four hours in the cold, the precipitate filtered off and freed, so far as possible, from any crystals of ammonium sulphate, placed in a dialyzer and dialyzed just so long and no longer in running water, and then in distilled water, until all trace of the ammonium sulphate has disappeared. Crystals of thymol added to the solution to prevent any putrefactive change; the solution then made up to such bulk that 10 c. c. shall correspond to each c. c. of tuberculin employed. (Title, '*B*,' ten per cent.)"

"Modification *CB*: 2 c. c. of tuberculin dropped into 20 c. c. of absolute alcohol; the heavy precipitate filtered off in a quarter of an hour; the filtrate evaporated over a water-bath at a temperature preferably not over 40° C., and just sufficiently long to drive off all alcohol; the residue taken up in 12 c. c. of distilled water, placed in a dialyzer and dialyzed for two hours in a running stream of water. Quantity made up to 20 c. c., including 2 c. c. of pure glycerin, used for preservative purposes; a few crystals of thymol added. (Title, '*CB*,' ten per cent.)"

TREATMENT WITH SUBCUTANEOUS INJECTIONS OF HUNTER'S MODIFIED TUBERCULIN.

No. of case, sex, and age.	Patient's history and physical examination at beginning of treatment.	Patient's weight, daily sputa, inoculation used, date when begun.	Duration of treatment, weight, and sputa, to date.	Physical examination at present date.
1. Male, 42.	Profuse hæmoptysis 5 years ago; pleurisy 3 years ago; night-sweats and cough since, with loss of 40 lbs. in weight. Physical signs: Slight retraction beneath right clavicle. Evidence of cavity in first interspace; also very abundant largish moist râles at this site. Abundant subcrepitation from first space to base. Posteriorly, same side, abundant subcrepitation, with larger râles, over supraspinous fossa. Abundant subcrepitation over whole of scapular region. Patient apyretic.	Jan. 13, 1892; weight, 134 lbs. Sputa, $\frac{3}{3}$ iv, daily average. "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 141½ lbs. Sputa, $\frac{3}{3}$ j, daily average. "B." 0.198 gm. to increase by 0.002 gm. daily.	<i>April 25th.</i> —Physical signs: Marked retraction, directly beneath right clavicle. Signs of cavity distinctly less marked, and it is apparently nearly dry. Scanty subcrepitation in second space; below this point, no adventitious sounds present. Posteriorly, adventitious sounds absent over supraspinous fossa and marked diminution of subcrepitation over scapular region. Patient apyretic; no night-sweats. <i>Very marked improvement.</i>
2. Male, 47.	History of 18 months; sputum occasionally tinged with blood; absence of night-sweats. Physical signs: Consolidation without crepitation over first and second right spaces and over supraspinous fossa. Posteriorly, subcrepitation over interscapular region. Left lung, feeble respiratory murmur, with scanty subcrepitation beneath clavicle and over supraspinous fossa. Evening temperature occasionally 100°.	Jan. 14, 1892; weight, 122 lbs. Sputa, $\frac{3}{3}$ j, daily average. "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 125 lbs. Sputa, $\frac{3}{3}$ j, daily average. "C. B." 0.092 gm. to increase by 0.002 gm. daily.	<i>April 25th.</i> —Physical signs: Practically the same as on first examination. Evening temperature occasionally 100°. <i>Condition stationary.</i>
3. Female, 32.	History of cough and occasional hæmorrhage for past 2 years. Physical signs: Dullness, with rather abundant subcrepitation in first right interspace; scanty subcrepitation in second space. Dullness, with moderate subcrepitation posteriorly, over supraspinous fossa and scapular region. Patient apyretic.	Jan. 17, 1892; weight, 105 lbs. Sputa, $\frac{3}{3}$ j, daily average. "C. B." 0.002 gm. to increase by 0.002 gm. daily.	April 21, 1892; weight, 107 lbs. Sputa, $\frac{3}{3}$ j, daily average. "C. B." 0.176 gm. to increase by 0.002 gm. daily.	<i>April 21st.</i> —Physical signs: Dullness with scanty subcrepitation in first space; absent in second. Dullness with scanty subcrepitation over supraspinous fossa and scapular region. Little appreciable difference from first examination. Patient apyretic. <i>Condition stationary.</i>
4. Male, 50.	Cough for past year; gradual loss of flesh and strength. Physical signs: Impairment of resonance over upper half of left chest, anteriorly, with fairly abundant subcrepitation over same. Posteriorly, impairment of resonance over upper half of left chest, with abundant subcrepitation over supraspinous fossa and scanty in areas over scapular region. Patient apyretic.	March 2, 1892; weight, 144 lbs. Sputa, $\frac{3}{3}$ j, daily average. "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 148½ lbs. Sputa, less than $\frac{3}{3}$ j, daily average. "B." 0.110 gm. to increase by 0.002 gm. daily.	<i>April 25th.</i> —Physical signs: Little appreciable difference in resonance over upper half of left chest since first examination. Crepitation has almost wholly disappeared anteriorly, and is practically absent posteriorly. Patient apyretic. <i>Marked improvement.</i>
5. Male, 32.	Hæmorrhage 5 years ago and another 3 years ago, very profuse. Since latter, unable to work, and has lost 40 lbs. in weight. Treated with tuberculin in Presbyterian Hospital a year ago, and apparently improved temporarily. Physical signs: Diffuse infiltration upper lobes of both lungs, with abundant subcrepitation at apices and scantier over remainder of affected regions. Most marked, right apex; occasional night-sweats. Patient apyretic.	March 2, 1892; weight, 123 lbs. Sputa, $\frac{3}{3}$ j, daily average. "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892, weight, 119 lbs. Sputa, $\frac{3}{3}$ j, daily average. "B." 0.078 gm. to increase by 0.002 gm. daily.	<i>April 25th.</i> —Physical signs: No appreciable difference from first examination. Occasional night-sweats. Patient apyretic. <i>Condition stationary.</i>
6. Male, 33.	Cough for 3 months; no hæmoptysis, no night-sweats. Physical signs: Impairment of resonance, with loss of vesicular respiration over right infraclavicular region. Abundant subcrepitation in second and third spaces. Similar signs over whole left chest anteriorly; in less degree also over left supraspinous fossa and scapular region. Slight pyrexia; evening temperature, 100°–100.2°.	March 3, 1892, treatment begun—March 21st, weight, 132 lbs. Sputa, $\frac{3}{3}$ ss., daily average. "B." 0.002 gm. to increase by 0.002 gm. daily.	April 25, 1892; weight, 135 lbs. Sputa, none. "B." 0.100 gm. to increase by 0.002 gm. daily.	<i>April 25th.</i> —No appreciable difference in impairment of resonance over affected regions. Subcrepitation scanty at present over right chest, and absent over supraspinous fossa and scapular region, left. Anteriorly, same lung, no appreciable difference from first examination. Patient apyretic since March 18th. <i>Improvement.</i>
7. Male, 41.	Cough for 6 months; no hæmoptysis, no night-sweats; gradual loss of flesh. Physical signs: Impairment of resonance, slightly prolonged and high-pitched expiration, with abundant subcrepitation in first two spaces, left; scanty, fine crepitation below. Same signs over supraspinous fossa as beneath clavicle; over upper half scapular region, scanty crepitation after cough. Slight pyrexia; occasional evening temperature, 100°.	March 3, 1892; weight, 135 lbs. Sputa, $\frac{3}{3}$ ss., daily average. "B." 0.002 gm. to increase by 0.002 gm. daily.	April 18, 1892; weight, 135 lbs. Sputa, none. Discharged, through desire and ability to go to work.	<i>April 25th.</i> —Impairment of resonance over first two spaces. Respiration feeble, but expiration not prolonged or increased in pitch. <i>Entire absence of all adventitious sounds over whole of left chest, anteriorly and posteriorly.</i> Patient continuously apyretic since March 18th. <i>Disease at present arrested.</i>

## TREATMENT WITH SUBCUTANEOUS INJECTIONS OF GUAIACOL RAPIDLY INCREASED.

No. of case, sex, and age.	Patient's history and physical examination at beginning of treatment.	Patient's weight, daily average of sputa ( $\bar{x}$ ), when guaiacol $\bar{m}j$ , increasing $\bar{m}j$ daily, was begun; date.	Duration of treatment, weight, and sputa, to date.	Physical examination at present date.
1. Female, 17.	Cough for 10 months; progressive loss of flesh and strength; no hæmoptysis; moderate night-sweats. Physical signs: Excavation at right apex anteriorly, with consolidation below; posteriorly, same lung, consolidation with numerous large râles and abundant subcrepitation over whole of scapular region, below fine crepitation. Left, anteriorly, moderate consolidation at apex, without crepitation. Advanced laryngeal disease. Marked hectic; evening temperature, $102^{\circ}$ - $103^{\circ}$ .	Weight, Feb. 27, 1892, $70\frac{1}{2}$ lbs. Average daily sputa, 3 ss.-3 j. Guaiacol, 0.05 gm. daily, to increase 0.05 gm. daily to 1 gm.	March 20, 1892, 71 lbs. Average daily sputa, 3 j-3 ij. Guaiacol, 1 gm. reached to-day; discontinued.	<i>March 20th.</i> —Physical signs: Progressive increase of lesions; night-sweats. Marked hectic; evening temperature, $102^{\circ}$ - $103^{\circ}$ .
2. Female, 30.	Hæmoptysis 3 years ago; present history of cough, 3 months; progressive loss of flesh and strength; no night-sweats. Physical signs: Dullness, prolonged and high-pitched expiration over left infraclavicular region, with very abundant subcrepitation. Same signs posteriorly over upper half of left lung. Right, similar signs, less in degree, anteriorly and posteriorly over upper half. Slight pyrexia; evening temperature, $100^{\circ}$ .	Weight, Feb. 27, 1892, $91\frac{1}{2}$ lbs. Average daily sputa, $\bar{x}$ j. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, $91\frac{1}{2}$ lbs. Average daily sputa, $\bar{x}$ j- $\bar{x}$ ij. Guaiacol, 1 gm. daily for 37 days.	<i>April 25th.</i> —Physical signs: Little appreciable difference from first examination, except subcrepitation now heard over whole left lung posteriorly. No night-sweats. Slight evening temperature.
3. Female, 24.	Pleurisy, right side, 3 years ago. Empyema same side 1 year ago, exsection of rib; cough and frequent hæmoptysis since; night-sweats. Physical signs: Large antrum in first right space, nearly dry. Moderate consolidation, without crepitation, in second space. Consolidation, apex, same lung, posteriorly, without crepitation. Patient apyretic.	Weight, Feb. 27, 1892, 135 lbs. Average daily sputa, 3 ij- $\bar{x}$ ss. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, 141 lbs. Average daily sputa, 0- $\bar{x}$ ss. Guaiacol, 1 gm. daily for 37 days.	<i>April 25th.</i> —Physical signs: Anteriorly, no appreciable difference from first examination; posteriorly, moderate subcrepitation at apex and over upper half of scapular region. Patient apyretic; occasional night-sweats. Marked improvement in general condition.
4. Female, 44.	Pneumonia 3 years ago; cough since; no hæmoptysis; no night-sweats at present. Physical signs: Consolidation, with fairly abundant subcrepitation at both apices. Subcrepitation also present over upper half right scapular and upper third left scapular regions. Slight pyrexia; occasional evening temperature, $100.2^{\circ}$ .	Weight, Feb. 28, 1892, $91\frac{3}{4}$ lbs. Average daily sputa, $\bar{x}$ ss.- $\bar{x}$ j. Guaiacol, 0.05 gm. daily to increase 0.05 gm. daily to 1 gm.	April 25, 1892, 90 lbs. Average daily sputa, $\bar{x}$ ss. Guaiacol, 1 gm. daily for 37 days.	<i>April 25th.</i> —Physical signs: No appreciable difference from first examination; no night-sweats. Occasional evening temperature, $100.2^{\circ}$ - $100.3^{\circ}$ .
5. Female, 32.	Grippe a year ago; cough since; no hæmoptysis; profuse night-sweats. Physical signs: Areas of infiltration throughout upper lobe, right lung, with abundant subcrepitation. Areas of infiltration upper lobe, left lung, with abundant subcrepitation and evidence of beginning excavation at apex. Hectic; evening temperature, $101^{\circ}$ - $102^{\circ}$ .	Feb. 28, 1892, 72 lbs. Sputa, $\bar{x}$ ij-iv, daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 12, 1892, 0.60 gm. Weight, 72 lbs.; sputa, $\bar{x}$ ij-iv.	March 15, 1892, guaiacol by mouth, $\bar{m}x$ ; $\bar{m}iv$ daily average. March 24th, $\bar{m}ij$ daily in pill, not increasing. April 1, 1892, weight, 64 lbs. April 6, 1892, sputa, $\bar{x}$ iv-v.	<i>April 1st.</i> —Physical signs: Progressive increase of lesions; moderate sweats. Treatment apparently some effect on sweats, none on fever. Died April 7, 1892.
6. Female, 46.	History of 10 months; a single hæmoptysis; night-sweats almost continuously. Physical signs: Large antrum, apex left lung, with impaired resonance and abundant subcrepitation to base anteriorly. Posteriorly, areas of subcrepitation to base. Beginning disease at right apex. Hectic; evening temperature, $101^{\circ}$ - $102^{\circ}$ .	Feb. 28, 1892, $95\frac{1}{2}$ lbs. Sputa, $\bar{x}$ j-ij, daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 9, 1892, 0.45 gm. Weight, $93\frac{3}{4}$ lbs.; sputa, $\bar{x}$ ij-iii.	Treatment discontinued before maximum dose reached; no further treatment. March 24, 1892, weight, $96\frac{1}{2}$ lbs. March 31, sputa, $\bar{x}$ ss.- $\bar{x}$ ij.	<i>March 10th.</i> —Progressive increase of lesions. Treatment apparently some effect on night-sweats, none on fever. Died April 1, 1892.
7. Male, 31.	Typical history since last November; several hæmoptyses; no night-sweats. Physical signs: Feeble respiratory murmur, with abundant subcrepitation over whole of right lung, anteriorly, and upper half of scapular region. Similar signs in slightly less degree over upper lobe left lung anteriorly and posteriorly. Pyrexia; evening temperature, $101^{\circ}$ - $102^{\circ}$ .	March 2, 1892, 92 lbs. Sputa, $\bar{x}$ vij-xjss., daily average. Guaiacol, 0.05 gm. daily; increasing 0.05 gm. daily. March 21, 1892, 1 gm. for 2 days. Weight, $88\frac{1}{2}$ lbs.; sputa, $\bar{x}$ vij.	March 22, 1891, guaiacol carbonate, gr. vj daily by mouth. April 12, 1892, weight, $86\frac{1}{2}$ lbs. Sputa, $\bar{x}$ iij; treatment stopped. April 19, 1892, guaiacol pill, $\bar{m}vj$ daily; increasing, $\bar{m}iij$ . April 25, $\bar{m}xxvij$ ; weight, 88 lbs.; sputa, $\bar{x}$ iij.	<i>April 25th.</i> —Physical signs: Very similar to those of first examination, except subcrepitation heard over whole of left lung anteriorly and posteriorly; no night-sweats; pyrexia. Evening temperature, $100^{\circ}$ - $101^{\circ}$ . General condition worse.

These modifications were prepared for me in the chemical laboratory of the College of Physicians and Surgeons.

My desire to test the practicability of employing a very large daily dosage of the creasote preparations, and to determine, if possible, any advantage which this method

might possess over their use in smaller quantities, has been fulfilled in a measure.

Several of the patients selected for this treatment presented in a well-marked degree many of the symptoms—*viz.*, hectic, sweats, etc.—attributed to the toxic influence of the

products of the bacillus, and were well adapted, therefore, to test the effect of creasote upon such manifestations.

It will be seen in the tabulated record that seven cases have been treated with subcutaneous injections of guaiacol, rapidly pushed to a daily dosage of one gramme, and five cases with creasote by the mouth, also rapidly increased to six grammes daily.

In four of the former cases there has been little if any appreciable change in the physical signs of disease. In one of these, however, the general condition has greatly improved, and there has been a gain in weight of eight pounds. In one the weight has decreased by a pound and three quarters; in one there has been a loss of four pounds; in one the weight has remained stationary.

In two of these cases the daily sputum has slightly increased in amount; in two it has slightly diminished.

In the three remaining cases there has been a progressive increase of the pulmonary lesions. No influence upon hectic, when present, has been observed. Night sweats, however, have been affected favorably.

In a single patient, suffering from chronic diffuse nephritis (confirmed by autopsy), a marked increase in the albuminuria was observed when a daily dosage of one gramme was reached. The treatment was then discontinued, and the albuminuria gradually diminished. In no other case treated either with guaiacol or with creasote has any trace of albumin appeared in the urine, in examinations made every other day. In a single case, when the maximum dose of guaiacol was reached, the urine became dark in color and very similar in appearance to urine containing carbolic-acid products.

Dr. Ely's report on the enumeration of tubercle bacilli in the daily sputum of several patients treated with guaiacol contains observations of interest and practical import. It indicates the possibility of incorrect conclusions even from the best method at our command for this purpose; also the absence of bacilli, from time to time, in the sputum of patients suffering from grave pulmonary tuberculosis.

In Cases II and IV, where there has been no apparent increase in the lesions and the general condition has remained stationary, the number of bacilli has greatly diminished.

In Case VII, in which the area of disease has slightly increased and the general condition has deteriorated, the bacilli have greatly increased in number.

In the cases treated with creasote there has been no appreciable difference in the physical signs of disease up to the present date in two. In these there has been a gain of one pound and a loss of three pounds, respectively. In the three remaining cases there has been a progressive increase of the lesions.

The effect of a very large daily dosage of creasote upon "hectic" and sweats corresponds to that noted in the use of guaiacol.

Entire tolerance of six grammes (over a drachm and a half) of creasote was exhibited by three of the five patients. One complained of gastric discomfort when a daily dosage of five grammes was reached, and one patient, who had suf-

fered from occasional nausea and vomiting previous to the administration of creasote, believed that these symptoms were increased by it. Several other patients at present in my wards are taking from four to six grammes of guaiacol daily, without gastric or intestinal discomfort.

Carbonate of guaiacol has been used so far as its supply permitted, and, aside from the advantage of being tasteless and odorless and only being decomposed by the intestinal secretions, it has seemed to me to very positively stimulate appetite.

The clinical conclusions which I have formed from a careful study of these cases are: That both creasote and guaiacol, in certain forms, can be given in very large doses with entire tolerance and without injurious effects; that such dosage apparently possesses no advantages over a much smaller one; and that it has no greater effect upon hectic and night sweats.

That subcutaneous injections of the drug possess no advantages over its administration by the mouth.

That whatever beneficial influence creasote may exert in pulmonary tuberculosis can be effected with a comparatively small dosage; and that favorable results can be expected only by its continuous and prolonged employment.\*

Dr. Ely's reports of his investigations on the germicidal action of creasote on the tubercle bacillus outside of the human body, and on the enumeration of bacilli in the daily sputum of patients treated with guaiacol, are appended.

For valuable assistance rendered me in my investigations, I desire to express my thanks to Dr. John Ely and Dr. Robert J. Devlin and to the gentlemen of the house staff of St. Luke's Hospital, Dr. Hollis, Dr. Rogers, Dr. Bunce, and Dr. Tuttle.

DR. ELY'S REPORT ON THE GERMICIDAL ACTION OF CREASOTE OUTSIDE OF THE HUMAN BODY.—Shortly after the revival of interest in creasote as a therapeutic agent in tuberculosis, the question arose as to the manner in which its beneficial effect was produced. Its general preservative and antifermentative properties had long been recognized and made use of in the arts, and the possibility of a similar inhibiting or germicidal action upon the specific germs of tuberculosis at once suggested itself. With a view to the solution of this problem, Guttman undertook a more definite determination of its germicidal action.

In his experiments nutrient gelatin was impregnated with creasote in proportions varying from 1 to 500 to 1 to 8,000. Into this seventeen different species of bacteria, thirteen of them pathogenic, were inoculated, and at the same time similarly inoculated tubes of ordinary gelatin serving as controls. The inhibiting action of creasote was found to vary considerably with different species, but in general a creasote proportion of 1 to 2,000 was found sufficient to prevent growth. The plan of experiment received slight modification in the case of the tubercle bacillus, blood serum being used as the nutrient medium, and the cultures,

\* Creasote was administered, without exception, in the form of what are known as the "enteric pills" of a well-known manufacturer. The nature of their protecting envelope I am ignorant of. Personal investigations of the effect of an artificial gastric juice upon the envelope showed that it was partially dissolved after one hour.

after inoculation, being placed in the thermostat at a temperature of 37° C. After several weeks, examination showed a meager growth in the tubes which had contained creasote in the proportion of 1 to 4,000 and 1 to 16,000; none in the others.

Since these experiments of Guttman, so far as I am aware, stand quite alone, it has been thought advisable to repeat them in so far as they relate to the tubercle bacillus, but in a slightly modified form. Instead of blood serum, glycerin-bouillon and glycerin-agar have been used as nutrient media, both of which have shown themselves particularly well adapted to the growth of the tubercle bacillus; and an aqueous solution of guaiacol, the principal ingredient of creasote, has been substituted for the alcoholic solution of creasote employed by Guttman in the preparation of his media.\*

These media were impregnated with guaiacol in the proportions of 1 to 1,000, 1 to 1,200, 1 to 3,000, and 1 to 4,000, and into them were introduced particles of a rapidly growing culture of the tubercle bacillus, other media, not containing guaiacol, being at the same time inoculated as controls. All were then sealed and placed in the thermostat at 37° C. At the end of seven weeks they were examined and the records tabulated below noted. It may be permissible to state here that every slightest indication of growth was carefully searched for, and that no record is made except where all the conditions necessary to the growth of tubercle bacilli were observed, so that the entry "No growth" in the tables below means literally what it says.

SERIES A.

*Glycerin-bouillon. Inoculated March 11, 1892; examined April 29, 1892.*

Control. Four flasks.	1 to 1,000. Two flasks.	1 to 2,000. Two flasks.	1 to 3,000. Three flasks.	1 to 4,000. Two flasks.
1. Moderate growth, not spreading much, but heaping.	1. No growth.	1. No growth.	1. No growth.	1. Apparently slight heaping up, thought to indicate very slow growth.
2. Luxuriant growth, overgrowing the whole surface of the bouillon.	2. No growth.	2. No growth.	2. No growth.	2. Slight heaping, though somewhat questionable.
3. Ditto.....			3. No growth.	
4. Moderate growth, heaping.....				

While fully recognizing the illusive nature of conclusions as to the value of therapeutic agents based upon periodical determinations of the number of tubercle bacilli in the sputum, it has been thought desirable to make such determinations in a number of cases treated with creasote and guaiacol.

The method employed for this purpose has been that recommended by Nuttall, the details of which are to be found in the *Bulletin of the Johns Hopkins Hospital*, vol. ii, No. 13, May-June, 1891.

\* Notwithstanding Guttman's statement to the contrary, it was thought possible that the alcohol necessary for the solution of the creasote might have a disturbing influence upon the experiment.

SERIES B.

*Glycerin-agar. Inoculated March 11, 1892; examined April 29, 1892.*

Control. Four tubes.	1 to 1,000. Five tubes.	1 to 2,000. Five tubes.	1 to 3,000. Five tubes.	1 to 4,000. Five tubes.
1. Very luxuriant growth, heaping and spreading.	1. No growth.	1. No growth.	1. No growth.	1. No growth.
2. Abundant growth, heaping and spreading.	2. No growth.	2. No growth.	2. No growth.	2. Very slight heaping and cloudiness at edges, as if growing sluggishly.
3. Moderate growth.	3. No growth.	3. No growth.	3. No growth.	3. Abundant growth.
4. Moderate growth.	4. No growth.	4. No growth.	4. No growth.	4. Very slight heaping; no apparent spreading.
	5. No growth.	5. No growth.	5. No growth.	5. Slight heaping and cloudiness at edges, as if slowly spreading.

Although this method is unquestionably the most accurate thus far proposed, it is nevertheless subject to great error, and the results are liable to be particularly misleading in cases in which the expectation is large and the number of bacilli small. Case VII, tabulated below, may be referred to as an example. About eleven ounces of sputum were eliminated daily. This was so viscid that its disintegration necessitated the addition of considerably more than an equal bulk of potash and water, so that once the total amount after dilution came to be 700 c. c. Since the dropper used delivers about 100 drops to the cubic centimetre, the contents of each drop (in this particular case) must be multiplied by 70,000 in estimating the total number of bacilli eliminated in twenty-four hours, and, of course, any error in the determination of the number of the bacilli to the drop is similarly multiplied; and where there are only a few bacilli to each drop, all may be overlooked in count-

*Results of the Determination of the Actual Number of Tubercle Bacilli in Twenty-four Hours' Sputum, by Nuttall's Method.*

Case.	Date.	Quantity of sputum in 24 hours.	Number of tubercle bacilli in 24 hours' sputum.
1	Feb. 24, 1892.	9 fl. dr.	227,684,401.
2	Feb. 24, 1892.	12 "	7,798,791.
	Mar. 23, 1892.	9 "	4,189,915.
	Apr. 6, 1892.	8 "	1,946,657.
	Apr. 29, 1892.	3 "	380,828.
3	Feb. 22, 1892.	1 "	579,792.
	Mar. 23, 1892.	3 "	About 100 fields carefully gone over without finding any bacillus. Whole drop then examined systematically, and still none found. Stain good.
	Apr. 29, 1892.	4 "	6,858,090.
4	Feb. 26, 1892.	6 "	7,707,033.
	Mar. 23, 1892.	6 "	274,246.
	Apr. 6, 1892.	4 "	202,149.
	Apr. 29, 1892.	2 "	270,228.
7	Mar. 17, 1892.	.....	100 fields carefully gone over; no bacillus. Whole drop; no bacillus. Stain good. A second cover of the same examined with the same result.
	Mar. 28, 1892.	10 fl. oz. and 6 fl. dr.	100 fields searched as above; no bacillus. Duplicate cover gives the same result.
	Apr. 6, 1892.	11 fl. oz. and 4 fl. dr.	1,307,395.
	Apr. 29, 1892.	11 fl. oz.	2,915,976.

ing fifty fields, or, on the other hand, a disproportionate number may-chance to be seen. Thus, in Case VII, while the majority of the fields contained no bacilli, one had three. A discrepancy of 100,000 or so is a matter of small import where many millions of bacilli are present, but may be very misleading when there are only a few hundred thousand.

### A CASE OF HEREDITARY NERVOUS GOUT.

By A. D. ROCKWELL, M. D.,  
NEW YORK.

Gout is a disease which, in the majority of instances, is so thoroughly dependent upon errors of food, drink, and exercise, and the influences of heredity, that its prevention and cure depend, for the most part, on the observance of strict hygienic methods.

It is within the experience of every physician that hereditary influences are alone sufficient, in many cases, to occasion attacks of gout. The victim may be most abstemious in all his habits of eating and drinking and active in his exercise, yet suffer at intervals from the characteristic pain and swelling of the smaller joints, clearly indicating the lithic-acid diathesis.

I have seen several cases of this character in which the loss of nervous tone was such a prominent feature that the term "nervous gout" seemed entirely applicable. There is one phase of the subject to which more consideration should be given in the study of electricity in its relation to gout, and that is the remarkable variation in the susceptibility of different individuals to its effects. One can appreciate fully this fact, however, only after long and varied experience. To say that some persons were not born to be treated by electricity is a strong expression, but thoroughly true. The observation was made years ago, and proofs of its substantial accuracy accumulate year by year without regard to the nature of the symptoms or the disease. There are, on the contrary, those whose tendencies and susceptibilities are quite in the opposite direction, and who respond most readily to any form of electrical treatment.

One of the most interesting evidences of the truth of this statement occurred in the person of a young man who first consulted me some ten years ago and whom I have been able to keep under observation ever since.

When I first saw him he was twenty-six years of age and was suffering from a distinct gouty swelling of the metatarsophalangeal articulation of the great toe and the large joint of the index finger.

He gave a history of direct hereditary transmission through several generations, and although both his father and grandfather had been high-livers and indulged freely in the choicest wines, he himself had been from childhood unusually abstemious in eating, had never touched liquor of any kind, and was an enthusiast along the line of athletic sports. He belonged, however, to the true neurasthenic type that is now so familiar to every observing physician. This was by no means his first attack. They were accustomed to come on at irregular inter-

vals, sometimes one or two years intervening between the paroxysms, and then again only a few months.

On each occasion the joints were exceedingly stiff, swollen, and painful, invariably keeping him from all active exercise for a month or six weeks.

The results that followed the use of electricity on many different occasions in his case conclusively proved that he was one of those "born to be treated by electricity." General faradization has always been followed by immediate and almost complete alleviation of pain, and has always very considerably shortened the attack.

In all the attacks from which the patient has suffered, six or seven in number, since electricity was first attempted, ten years ago, only once was he prevented from receiving the customary treatment.

On this occasion it was five weeks before he fully recovered, while in all previous and subsequent attacks three weeks was the limit of the duration of the disease.

Acute attacks of gout, however, depending upon errors of food and drink, combined with indolent habits, offer no encouraging field for the beneficial effects of electricity. It is indeed doubtful whether it would ever prove of sufficient service during the attacks in these ordinary cases to be worth the time and labor necessary.

Taking into consideration the catalytic and absorptive power of the galvanic current, it has been suggested that much could be accomplished through its use in dissipating the gouty concretions that form in the various joints of the body. Experience has not, however, confirmed the correctness of this suggestion. The deposits of urate of sodium resist with great persistency all external and mechanical methods of treatment, as well as the internal administration of remedies.

I have in past years treated many cases of this character, but I am bound to say that I have never yet seen a true calcareous deposit in the joints appreciably diminished by any form of electrical treatment. I have, however, known of actual damage being inflicted by a too confident and careless resort to the galvanic current.

In December last a gentleman called upon me, inquiring if electricity could do anything to relieve his hands and feet, stiff and crippled from repeated attacks of gout. That the urates had been deposited in large quantities was evidenced by the great deformity and unusual size of many of the joints, and especially those of the hands. The skin, as it stretched over the concretions, presented the characteristic bloodless and shining appearance, and looked as if, under provocation, it might entirely give way.

I told him that electricity could do nothing for him. Within a week he returned, saying that he had been assured by another that the galvanic current would certainly help him. Upon this assurance he submitted to two local applications of the current strong enough to occasion sharp burning and reddening of the skin. The almost immediate result was an excoriation, which is likely to be permanent. While the continuous pressure of the deposits might in time have caused ulceration, yet it is quite certain that this result was hastened by the injudicious treatment to which he had been subjected.

There is much truth in the expression that "he only has gout who will have it." Leaving heredity out of the question, it is an entirely preventable condition, and is brought

about in the majority of cases by grossly unhygienic methods of living.

Its prevention and cure depend, for the most part, on a return to proper methods of living, both as regards eating and drinking and exercise, and only in so far as electricity can be made to produce effects similar in kind to those obtained through muscular exercise is it of any therapeutic value in this disease. In those cases, therefore, where, from any cause, adequate active exercise is not practicable, the mechanical effects of the faradaic current, by the method of general faradization, or of the static induction current of electricity, are certainly indicated and are capable of service.

## SENILE GANGRENE OF THE TOES;

AMPUTATION AT THE LOWER THIRD OF THE THIGH;  
RECOVERY.

By M. S. KAKELES, M. D.,  
NEW YORK.

LAST March (1891) I was called to see a lady, seventy years of age, who had been confined to her bed for three months. It was on the 19th of the month when I first saw her and received from her the following history: For twelve years she suffered with pains in the lower left extremity, which she supposed were due to a varicose ulcer situated a little above the external malleolus which now and then healed over, but oftener was in an open condition. During the latter part of the three months that she was bedridden the ulcer had healed, but the pains persisted around the ankle joint and foot. She had been treated for rheumatism until a small dark spot appeared on the big toe, about a week before I first saw her. The physician then had diagnosed commencing gangrene, and ordered poultices to the parts; this had been kept, until I was called in.

On examining the patient, one would, from her appearance, have judged her to be ninety years old instead of seventy. Anæmic, haggard, and in a debilitated condition. Appetite poor. The pulse fairly good, and evidenced sclerotic condition of the vessels. The heart was weak. No murmurs. Lungs normal. There was no rise of temperature. The urine, from repeated examination, contained neither sugar, albumin, nor casts. The skin was wrinkled and in a flabby condition. Over the sacrum there was an abrasion of epidermis and cutis about the size of the palm of the hand, as result of continual pressure. The left big toe was entirely gangrenous, the second in an incipient stage of mummification. From her general appearance and debilitated condition, and from the character of the gangrene, there seemed to me at the time no hurry to amputate the foot, or even the toes, until the nature of the progress of the disease was well established and the patient been put in a better condition, although I had in view at the time that an amputation above the middle of the leg would give better results than removal of the toes or even the foot.

The first indication to be met was the extreme weakness of the patient, and I resolved to stimulate her for a few days with tonics and good nourishment, in order that she could better be able to withstand the shock of an amputation. The gangrenous toes were treated antiseptically, and the course of the disease carefully watched until it commenced to spread to the back of the foot.

As my patient had reacted well to the tonics (strychnine, iron, etc.), which had been given for two weeks, and the bed-sore taken on a healthy granulation, it then seemed that the time had arrived when amputation was imperative. The question was at what place.

Koenig, in his *Surgery*, gives three causes of senile gangrene.

1. As consequence of inflammatory stasis, resulting from some slight injury, in such patients who have exhibited symptoms of impoverished nutrition of parts—such as coldness and insensibility of toes, fingers, etc.

2. Less frequently as a consequence of marasmic thrombus of the capillaries without preceding inflammation which leads to localized mummification of skin and gradual spreading.

3. Still less frequently gangrene as result of embolus or localized thrombus in a large arterial branch.

I attributed in my patient the cause of the gangrene to that class due to thrombus in the capillaries, and, on account of the unhealthy condition of skin above the ankle, due to her chronic ulcer, thought to amputate above the seat of the ulcer—namely, the middle or upper part of the leg; but still the fear that my flaps might slough deterred me from taking this seat of election. The popliteal artery was also much sclerosed, which also led me to believe that the higher I would amputate (without forgetting the serious risks taken in removing so much of an extremity) the better chance I would have of avoiding a recurrence of the gangrene. I decided, therefore, after careful deliberation, that the prognosis would be far better by amputation above the knee than below, through a skin which in all likelihood, from its appearance, would have sloughed, and thus endangered my patient's life through septic infection.

On April 2d, as careful an aseptic operation (under a narcosis with the A. C. E. mixture) as could possibly have been done was performed through the junction of the middle and lower thirds of the femur. The circular method was used; the flaps sewed with silkworm gut, and three small drainage-tubes inserted—one at each end, and one in the middle of the wound. The stump dressed, and patient put to bed with a good pulse. She rallied well and primary union obtained, except where drainage-tubes were inserted. After four weeks the patient was walking around on crutches, and said she felt better than she had in the last twelve years. She left the city perfectly happy that she could once more walk about.

I report this case to confirm the value of Haidenhain's conclusions that amputation through the thigh, when once senile gangrene has commenced in the toes and spreads to the foot, is far better (barring contra-indications) than running the risk of rapid sloughing of flaps in a lower operation.

## IRREDUCIBLE UMBILICAL HERNIA

(OMENTAL) SIMULATING LIPOMA.

OPERATION.

By CAPTAIN H. P. BIRMINGHAM,

MEDICAL DEPARTMENT, U. S. ARMY,  
BOISE BARRACKS, IDAHO.

(Published by authority of the Surgeon-General.)

In October last Mrs. M. R., a laundress at this post, a woman of large build and very fleshy, consulted me about a tumor of the abdominal wall. She is a French Canadian with Indian blood, forty-seven years of age.

About ten years ago she first noticed a small lump a little to the left of the median line, near the umbilicus, which at times appeared to remain stationary and again would increase in size with considerable rapidity. She had some time previously been examined by two civilian physicians, who pronounced it a fatty tumor of the abdominal wall.

Upon examination, I found what appeared to be a lobulated growth nearly the size of an adult head, with a distinct pedicle when the patient was standing, but which seemed to flatten out

somewhat when she lay down. She gave no history of strain or traumatism of any kind at the time, although, after the operation, when it was explained to her what was found, she remembered being hurt by attempting to save a man from falling under the burden of a too heavy log, and of feeling a very acute pain in the abdominal wall at the time—a statement which, if made before the operation, would probably have saved me from an error in diagnosis. She also stated that the tumor began to grow shortly afterward, although she did not consider the accident a causative factor.

The location of the tumor seemed to be against its being of a lipomatous nature, but the general appearance and history pointed that way, and I was also influenced somewhat by an idea which prevails in the Northwest that people of the mixed type are more liable than others to lipomatosis.

I asked a physician from the neighboring town of Boise City to see the case with me, and, after a careful examination and the application of Nélaton's circumduction test, we concluded that it was a fatty tumor. As the patient was anxious for relief from the annoyance due to the weight and consequent dragging, I decided to operate, which I did on October 16, 1891, under conditions of strict surgical cleanliness.

Upon cutting through the integument I came upon what looked like a peritoneal sac, and soon discovered what I had to deal with. I opened the sac, and, upon introducing my hand, found that it contained omental fat only, from which the membrane proper had in great part disappeared. I found the whole mass firmly adherent at the neck and wholly irreducible. I separated the adhesions with some difficulty with my fingernails, and while so doing violent retching set in and several feet of small intestine were forced out through the ring and tightly and immovably held there. I then determined to remove the sac and its contents, which I did by doubly ligaturing them separately with aseptic silk, cutting them off close to the ring, and dropping the pedicles back into the abdominal cavity. In hastily separating the intestine from some adhering omentum I tore a hole in the mesentery, which caused a very free hæmorrhage, but which was readily controlled by hæmostatic forceps; two vessels were ligated with catgut. After returning the prolapsed gut, which had been protected by towels wrung out of hot, previously boiled water, I decided to attempt a radical cure, but, as the patient's condition was none of the best, whatever was done had to be done quickly, so I hastily passed a double silk ligature, in purse-string fashion, around the umbilical opening, well back from its cartilage-like border, drew it tight, tied it, and brought out the ends at the upper angle of the wound. I did this with the McBurney idea in view—that is, keeping the upper angle open and making it granulate from the bottom. The lower part of the wound was closed and a dressing of iodoform gauze applied.

There was a slight rise of temperature for several days, but there was no evidence at any time of other than a local peritonitis at the site of the purse-string suture. The opening at the upper angle of the wound continued to discharge, and was slow in filling up on account of the thick layer of abdominal fat. I irrigated it with Thiersch's solution, and latterly with one of weak permanganate of potassium. It is now completely closed, and there is a fine cicatricial boss with a broad base over the site of the former opening. The ligature came away on the twenty-fifth day. Of course, it is too soon to even conjecture what the ultimate result will be, but the patient says her "stomach" feels as firm as ever, and that she never felt better.

The amount of omentum removed must have weighed nearly three pounds, but, unfortunately, it, with the sac, was thrown away before I could secure it.

January 29, 1892.

THE  
NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MAY 21, 1892.

DR. LAUDER BRUNTON ON HÆMORRHOIDS.

DR. LAUDER BRUNTON lately read before the Medical Society of London a practical paper on the causes and treatment of hæmorrhoids and allied affections. According to the report of the discussion, as given in the *Medical Press and Circular* for March 16th, it was contended that this "lowly complaint, piles," should receive a larger degree of medical attention than was commonly the case, in order that in the end the surgeon should have to be called upon less frequently; and that, in fact, only when persistent neglect had increased the severity of the disorder beyond ordinary limits should there be recourse to surgical means. Unfortunately, the term "piles" is often applied to pathological states of the anal region that have little in common. The prophylaxis of the disorder has for this reason been clouded by discrepant views. Dr. Brunton seeks to put anal prophylaxis and rectal medication on a clearer and more even basis. He especially magnifies the causative influence of "chill." There are four regions of the human body that are particularly susceptible to cold—the nape of the neck, the abdomen, the shins, and the feet. The shins are a weak point seldom considered. There are many persons who would not think of going out into the cold, unless properly clad, who pass comparatively long periods in cold, sometimes damp, water-closets with important parts of their bodies entirely unprotected. Reflex contraction of rectal muscular tissue prevents the blood from finding its way back through the hæmorrhoidal veins, the obstruction taking place at the point where the veins pass through the muscular walls of the rectum.

The question of treatment with cathartics was discussed, reference being made first to the benefit derived from mercurial purgation followed by salines in the reduction of hepatic congestion. The author next showed that certain cathartic drugs—aloes, for example—would in large doses conduce to pile formation by unduly stimulating the muscular coats of the rectum; whereas in small doses they acted in a contrary way. Hepatic congestion from chill might also be relieved by applying hot-water bags to the back of the neck and over the liver. Persons who had piles might be benefited by accustoming themselves to emptying the rectum after supper, in order to secure rest in the recumbent posture afterward. The use of water for cleansing and at the same time allaying irritation was preferable to that of the somewhat harsh fabrics sold for the closet, but unsuitable for vigorous application to sensitive or to irritated parts. Dr. Brunton often advises the use of a pledget of absorbent cotton, dipped in a liquid preparation of hamamelis, since it both supports the parts and acts as a topical medication. The official extract and tincture, he thinks, have

not been so serviceable as some of the trademarked articles. The anal pad has been a means of great relief in some obstinate cases. The compound called "listerine," when suitably diluted, has been found by some practitioners an advantageous application.

MINOR PARAGRAPHS.

AWAY WITH THE HOLLOW PESSARY.

A HOLLOW Hodge pessary is an innocent-looking thing, and it is undoubtedly somewhat lighter than a solid one; but the weight of a hard-rubber Hodge pessary is not worth considering, whether hollow or solid, and the hollow article may do damage, as the writer of this article has reason to believe from an occurrence that is within his recent experience. Having removed a hollow pessary, when he was about to reinsert it, he found that, although it had been lying for several days in a disinfectant solution, it was decidedly odorous. Knowing that hard rubber ought not to acquire an odor incapable of being dissipated by washing with water, he was for the moment puzzled. He soon observed, however, that, although the instrument had been carefully dried on its exterior, it felt moist on further handling. On closer inspection, it was found to present a pin-hole opening, and it was evident that through this opening the secretions of the vagina had gained access to its interior. This conclusion was further confirmed by applying the test of succussion; on shaking the pessary, the presence of the liquid within it was abundantly evident. It was at once returned to the instrument-maker, and a solid pessary was substituted for it. The hollow Hodge pessary is not often met with in commerce, and, considering the danger to which, as this incident shows, a patient may be subjected by its use, it should no longer be put upon the market.

A REMEDY FOR CHRONIC RHEUMATIC ARTHRITIS.

ACCORDING to Mr. Hugh Lane, in his recent work on *Rheumatic Diseases*, the following prescription was found of such service among the pensioners of Chelsea Hospital who suffered from chronic rheumatic arthritis that Lord Anson gave three hundred pounds for the liberty to give publicity to it: ℞ Honey, ℥ xvj; sulphur, ℥ j; cream of tartar, ℥ j; rhubarb, ℥ iv; gum guaiaci, ℥ j; nutmeg, No. j. Misc. The patient took two tablespoonfuls in a small tumbler of hot white wine and water when going to bed, and the same quantity before rising in the morning, remaining in bed until any perspiration that was occasioned had subsided. The treatment was continued until a perceptibly good effect had ensued, when only one teaspoonful was administered at a dose until the mixture was used up.

THE WOMAN'S HOSPITAL AND THE ALDERMEN.

THE Board of Aldermen have a deep interest in the prosperity of the Woman's Hospital in the State of New York. This is shown by the following report of proceedings at a regular meeting last week: "A resolution was passed by the aldermen permitting the sale of the property at Lexington Avenue and Fiftieth Street, now occupied by the Woman's Hospital, on condition that the hospital authorities in their new location set aside fifty free beds to be at the disposal of the aldermen." After the meeting adjourned, one of the friends of the hospital suggested that at the next session the City Fathers should vote that the twelve signs of the zodiac should be "set aside" at the disposal of the aldermen. It is a new feature in the politician's evolution for him to "strike" a hospital for "free beds."

## EPISPADIAS SUBSEQUENT TO INJURY IN COPULATION.

THE fourth annual report of the Senev Hospital, of Brooklyn, contains a brief note regarding an alleged acute gangrenous inflammation of the penis due to injury during coition. The corpora cavernosa took on violent inflammatory action, and the greater part of their substance sloughed away. The treatment, by incision, removal of necrotic tissue, and iodoform dressings, was followed by a gradual repair. Deformity and epispadias marked the condition of the penis at the time of the patient's discharge. A plastic operation has been proposed for the relief of the man's embarrassment from the flow of his stream of urine from the top of the deformed member, but he has not yet returned to accept the offer.

## DEATHS BY INFLUENZA.

DR. BALOH, the secretary of the State Board of Health, estimates that 10,000 deaths, in New York State, were chargeable to influenza and its sequels in the winter quarter of 1892. The local diseases appear to bear the brunt of a largely increased mortality, but influenza is probably the genuine cause.

## THE DIGNITY OF THE PATIENT.

It is reported that a physician in Germany has lately been sentenced to imprisonment for an indignity offered to a patient affected with hysteria. The incident serves to illustrate the principle that, while it may often be necessary to shock a patient, either physically or mentally, nothing ever warrants an affront from physician to patient.

## ITEMS, ETC.

**The New York State Medical Association.**—At the eighth annual meeting of the Fifth District Branch, to be held in Brooklyn on Tuesday, the 24th inst., under the presidency of Dr. H. Van Hoesenberg, of Kingston, papers are to be presented as follows: The Limitations for Vaginal Hysterectomy in Malignant Disease of the Uterus, by Dr. J. E. Janvrin (the discussion to be opened by Dr. George T. Harrison); Retention of Menstrual Blood from Imperforate Hymen, by Dr. J. R. Van derveer; Voluntary Patients in Asylums for the Insane, by Dr. W. D. Granger; Acute Catarrh of the Middle Ear as a Complication of la Grippe, by Dr. Samuel W. Smith; and Brown-Séquard's Paralysis resulting from Syphilis, by Dr. S. T. Armstrong.

**The Medical Society of the State of New York.**—The business committee for the meeting of February, 1893, has been organized by the appointment of Dr. Seneca D. Powell, of No. 12 West Fortieth Street, New York, as chairman, and Dr. William Maddren, of Brooklyn, and Dr. John O. Roe, of Rochester, as associates. The programme for the scientific work of the session is said to be already well advanced in its preparation.

**The New York Society for the Relief of Widows and Orphans of Medical Men** celebrated the fiftieth anniversary of its organization at a dinner at the Academy of Medicine on Saturday evening, the 14th inst. The secretary read a summary of the work done by the society, showing it to be an exceedingly well managed and useful organization.

**The New York Polyclinic.**—Dr. Christian A. Herter has been appointed lecturer on the anatomy and pathology of the nervous system.

**The Northwestern Medical Society of Philadelphia,** which has been in existence two years, meets on the second Tuesday of each month.

**Change of Address.**—Dr. C. H. Althaus, to No. 1024 Bushwick Avenue, Brooklyn.

**The Death of Dr. Rutson Maury** took place on May 5th, after less than a week's illness of pneumonia. He was born in North Carolina

thirty-seven years ago. Nearly all his life had been spent in New York. He was an alumnus of the College of the City of New York of the class of 1883, and of Bellevue Hospital Medical College of the class of 1887. At the latter institution he passed at the head of the class, and availed himself of an internship at Bellevue. About two years later he entered practice, being associated with Dr. W. T. Lusk. His death took place at St. Luke's Hospital.

## Society Meetings for the Coming Week:

MONDAY, *May 23d*: Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement; Baltimore Academy of Medicine.

TUESDAY, *May 24th*: New York State Medical Association, Fifth District Branch (annual—Brooklyn); Connecticut Medical Society (first day—New Haven); Association of American Physicians (first day—Washington); New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society (private); Buffalo Obstetrical Society.

WEDNESDAY, *May 25th*: Connecticut Medical Society (second day); Association of American Physicians (second day); New York Surgical Society; New York Pathological Society; American Microscopical Society of the City of New York; Metropolitan Medical Society (private); Medical Societies of the Counties of Albany and Monroe (annual—Rochester), N. Y.; Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Philadelphia County Medical Society.

THURSDAY, *May 26th*: Connecticut Medical Society (third day); Association of American Physicians (third day); New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, *May 27th*: Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, *May 28th*: New York Medical and Surgical Society (private).

## Letters to the Editor.

## THE POLYSCOPE AND THE DIAPHANOSCOPE.

[Translation.]

14, RUE VIVIENNE, PARIS, April 11, 1892.

To the Editor of the *New York Medical Journal*:

SIR: In the *Revue illustrée de polytechnique médicale et chirurgicale* for March 31, 1892, I read a letter addressed to the *New York Medical Journal* by Dr. Max Einhorn, who seeks to establish priority over Dr. Hugo J. Loebinger for an electrical apparatus making it possible to illuminate the stomach and even the large intestine in man.

The French journal comments upon its translation of the letter into our language. It asks justly how the observer can procure any information from illumination thus produced, and it remarks that experiments in diaphanosecopy were long ago made in France without any appreciable positive results.

Will you allow me, Mr. Editor, to join in the discussion and to furnish Dr. Loebinger with the historical data that he desires? Perhaps I am competent to do it, for, being perfectly familiar with the chief fruitless attempts that had been made in Europe, in 1869 I invented certain electrical appliances which I called *polyscopes*, which not only illumined the interior of the stomach, the large intestine, and certain other natural cavities of the human body, but allowed of viewing the interior of these organs *directly, and not by transparency*. My polyscopes were

honored with the medal of progress at the Vienna International Exposition in 1873. They were briefly described in your country by the *Scientific American* for September 21, 1878.

I do not wish to insist on the services that my *electrical polyscopes* have rendered in the domain of biology; I will only say, in order to show that these appliances really exist and that for many years they have rendered signal services to medicine, that with them Professor Guyon has shown to his pupils the normal and morbid states of the mucous membranes of the rectum and bladder; that Professor Lallier and the illustrious Professor Péan have made use of them for illuminating deep cavities from which they have removed tumors; and that Professor Collin, of Alfort, since 1876, with the aid of my polyscope, has been demonstrating to his pupils the interior of the ox's stomach in order to teach them the digestion of that ruminant. Introducing successively a frog and a leech into the organ, he has shown them the disorders caused by the latter animal.

I shall not further insist upon the experience, now classical in France, Germany, and Austria, of my luminous fishes. Dr. Georges Barrall's work (chapter vii, second part, pp. 291 to 320), which I have the honor of sending you, will give you the amplest data on all these subjects. *Les nouvelles découvertes en électricité* (such is the title of the work) will also show you how the use of my electric polyscopes has been extended even to extra-organic investigations. It is thus that they were found of service in inspecting and testing the bores of cannon and shell at the arsenal St.-Thomas d'Aquin, the interior of casks, the slides of steam-engines, hydraulic elevators, and bore-holes, (in which case they are called *orygmoscopes*).

They are still used daily in the national powder magazines of Sevrans-Livry and Ripault, in the schools of practical artillery and engineering at Versailles, Toul, Belfort, Verdun, and Epinal, and the foundries and ship-yards of the Mediterranean, etc.

Dr. Loebinger's pelveoscope, therefore, was long ago—more than twenty years ago—preceded by the Trouvé electric polyscope, which, used upon the rectum, has for many years been known as the rectoscope. My electric gastroscope also leaves Dr. Max Einhorn's gastrodiphane just twenty years behind it.

There is no further occasion, evidently, to speak here of diaphanoscopy. As a diagnostic procedure, it was long ago condemned. In 1867 Mr. Bruch, of Breslau, illuminated the interior of the mouth with his stomatoscope; at that time, also, Dr. Millet made experiments in Paris in diaphanoscopy upon the stomach of animals. In 1868 Dr. Lazarevic, of Karkoff, published a brochure upon the subject. No undertaking in this direction has succeeded, and none could succeed.

Such being the case, I certainly believe that I was the first not only to illumine the bodily cavities in a really practical way, but also to see directly and distinctly what I illumined. As the *Revue illustrée de polytechnique médicale et chirurgicale* justly says, Dr. Einhorn seems to have wholly forgotten to take this last, but chief, precaution.

Dr. Bardet, the author of a *Traité d'électricité médicale* (1884) very much esteemed in France, recognizes as follows the progress achieved from the point of view of medical diagnosis by my polyscopic apparatuses: "M. Trouvé, auquel on doit tant de découvertes précieuses autant qu'ingénieuses, est certainement celui des électriciens qui a le plus fait pour la médecine. Ses appareils ont été copiés plus ou moins servilement à l'étranger; mais c'est à lui seul que revient l'honneur d'avoir le premier réussi à éclairer les cavités profondes de l'économie en portant le foyer lumineux au sein même de l'organe, marquant ainsi un grand progrès sur tous les autres appareils précédemment imaginés." G. Trouvé.

## Proceedings of Societies.

### NEW YORK SURGICAL SOCIETY.

Meeting of November 25, 1891.

The President, Dr. ARPAD G. GERSTER, in the Chair.

**Osteosarcoma of the Jaw.**—Dr. CHARLES McBURNEY showed a man, sixty-two years of age, who had come to him two weeks and a half before with an osteosarcoma of the left upper jaw. He had felt some hesitation in operating because of the extensive encroachments of the tumor. The operation was, however, done in the usual way. The growth, being too soft to remove *en masse*, was taken away piecemeal with scissors and curette. The speaker wished to urge the advantage of preliminary tracheotomy when operating upon such very vascular tumors, as this proceeding allowed one to pack the lower pharynx with sponge and so entirely avoid the entrance of blood into the trachea. Etherization also went on uninterruptedly through the tracheal tube. It seemed to him that the plan he had followed was simpler and better than that dependent upon the use of the tampon of Trendelenburg. The preliminary tracheotomy was rapidly done, and there was no irritating cough, such as usually occurred when one made use of the tampon of Trendelenburg. As to the method of nutrition for these patients, the speaker again urged consideration for rectal alimentation exclusively for a period of some days after such operations about the air passages. In this old man it had been carried on for three days without any evidences of weakness from lack of food. He had been thus fed every four hours, and had been given an ounce of whisky, an egg, half a drachm of salt, and four ounces of water each time.

**Osteoplastic Resection of the Upper Jaw for Nasopharyngeal Polypus.**—Dr. McBURNEY also reported the case of T. E. W., twenty-five years of age, who, eight months previous to treatment, had first noticed the signs of his disease, the first indication being stiffness of the articulation of the lower jaw and pain on the right side of the head. Severe neuralgia followed, then obstruction of the nares and difficulty in swallowing. Severe epistaxis occurred on several occasions. The right nostril was found occluded and the right infra-orbital region was slightly prominent. With the finger behind the soft palate a large smooth tumor could be felt high in the pharynx. This could also be seen with the rhinoscopic mirror. Believing that the tumor was one of naso-pharyngeal origin and not one involving the upper jaw, and appreciating that much room would be required to remove it successfully, the speaker determined to do an osteoplastic resection of the right upper jaw. As hæmorrhage from such vascular tissue was to be feared, preliminary tracheotomy was done in order that the lower pharynx might be plugged during the operation. The superficial incision extended along the lower border of the orbit, then downward beside the nose into the nostril, and again through the upper lip. The flap was turned back and then a section of the hard palate made in the median line with the knife through mucous membrane and periosteum. Also, transversely from the posterior end of this incision, an incision was made to a point near the last molar tooth. An incisor tooth was drawn and the bone divided with the chisel at all points except its upper outer angle. The right upper jaw was then easily pried outward, fully disclosing the naso-pharyngeal space, which was filled by the large tumor. The tumor was readily removed with scissors from its base of attachment to the extreme upper pharyngeal roof. Bleeding was active, but was readily controlled by pressure, and, the pharynx having been previously packed at its lower end with sponges, no blood entered the trachea. The

base of the tumor attachment was cauterized and the jaw swung back into place and stitched at various points. Primary union took place throughout, but on the fifth day a sharp secondary hæmorrhage occurred, which was promptly stopped by partially separating the jaw and packing the upper pharynx with gauze. After this, recovery was rapid and complete.

Dr. J. A. WYETH thought that there was little merit in discussion when a case was so successful. Perhaps he should question whether there had existed the necessity for preliminary tracheotomy. He had many times removed the jaw for malignant and non-malignant disease, and had never had to resort to tracheotomy. He held, as he had before urged, that, by giving a position of lateral declination to the patient's face without the head being pitched over the back of the table, the blood would run out effectually and there would be no danger.

Dr. J. D. BRYANT said that, in considering what operation should be done, it was well to recall the fact that the dangers from loss of blood were comparatively trifling. He had collected two hundred and fifty-four cases of excision of the jaw. There were two hundred and thirty cases of excision of a single jaw, and one hundred and eighty-eight of the patients had made a perfect recovery. Thirty-three had died from hæmorrhage, but only nine from primary hæmorrhage. In twenty-four cases in which both jaws or the principal portions of both were removed none of the patients had died. In the operations the speaker had done, to expose pharyngeal growths or for disease of the jaw itself, he had ligated the external carotid. The fact that Dr. McBurney's patients were present and that tracheotomy had acted so well was evidence in its favor. Still, the object was to get rid of the blood and insure against its entrance into the air passages. Ligation of the external carotid did this and avoided the additional danger of opening the trachea. In the operations he had done the hæmorrhage had been trifling.

Dr. McBurney explained that he was by no means a believer in preliminary operations of any kind, unless they were required. In the case of a large tumor with soft and very extensive attachments, such as he had described, he thought the method he had followed advisable.

**Fracture of the Temporal Bone involving the Petrous Portion; Extradural and Subdural Hæmorrhage; Fistulous Communication with the Lateral Ventricle; Operation; Recovery.**—Dr. C. BRIDDON presented a man, aged twenty-six, who had been admitted into the Presbyterian Hospital in his service. The man had fallen from a hay-loft, a distance of twelve feet, alighting on his head. It was thought that at the same time he had been struck on the head with a heavy piece of iron. On his admission his temperature was 100.5° F.; his pulse 80, full and regular; and his respiration 34. He was in a condition of stupor, but could be aroused, and was irritable. The pupils were equal, but dilated. There was a sero-sanguinolent discharge from the right ear. Examination of the scalp revealed a superficial contused wound in the right post-parietal region, but no evidence of depression. There was no paralysis. The reflexes were preserved. The head was shaved and an ice-cap applied. On the following day the temperature was normal, the serous flow from the ear continued profuse, and the mental condition was sluggish. There were noted dilatation of the left pupil, deviation of the tongue to the left, obliteration of the right naso-labial fold, left conjugate deviation of the optic axes, and marked weakness of the left arm. The mental condition improved somewhat, but the memory was impaired, and the flow from the ear persisted up to the morning of September 7th, when he complained of a severe pain in the right side of the head and neck, and had become stupid. Thus, after a lucid interval of eight days, there supervened manifestations of compression, the patient lying as if in a tranquil sleep,

except during paroxysms of delirium, lasting sometimes an hour, and followed by excruciating pain in the head. The pulse was slow and regular, except on exertion, when it would reach 130. When aroused, he would open his eyes and mutter. The respirations were slow and deep, sometimes stertorous. The left facial paralysis, the inequality of the pupils, the optic deviation, the partial paralysis of the left arm, and the progressively increasing stupor, with a temperature of 105°, all seemed to justify an immediate operation. On September 7th he was operated on under ether narcosis and with antiseptic precautions. By a curved incision the squamous portion of the right temporal bone was exposed. There was found a V-shaped fracture, the apex pointing downward, and the arms extending upward to the squamo-parietal suture; the apex was depressed about an eighth of an inch. This was elevated and removed, exposing a clot. The opening was enlarged to the extent of an inch and a half and the clot removed. Examination showed a fissure extending downward through the root of the zygoma into the petrous portion, but it could not be followed farther. The dura was opened and the brain substance found lacerated and contused. Several small clots and a good deal of broken-down brain material escaped. There was a considerable protrusion of cerebral substance through the opening. Two drainage-tubes were introduced, and the wound was dressed open. On the following day the patient responded intelligently to questions, but was delirious at times. The tubes were removed at the end of ten days. There was a protrusion of brain substance. Facial paralysis was still present, and there was complete deafness of the right ear. There was a continuous flow of cerebro-spinal fluid, the pillow being constantly soaked, and the liquid to be seen distilling from a small fistulous opening, situated in the center of the granulations covering the exposed brain. The amount that escaped every day was estimated at about two ounces and a half. On October 8th an aluminium probe was allowed to pass by its own weight into the sinus, a distance of two inches and a half, evidently entering the ventricle. The fluid was quite limpid and, after continuing for about two weeks, the flow gradually diminished, and in three weeks had ceased entirely. *Pari passu* with these changes the brain receded and cicatrization ensued. At the present time the wound was entirely healed, but the cicatrix was tender, and pulsation of brain could be detected over the area of the operation. No paralytic conditions remained except some obliteration of the naso-labial fold. One feature of extreme interest remained unexplained. Before this accident the patient had been the terror of the neighborhood in which he lived, frequently coming in contact with the police. Since his recovery his character had entirely changed; he had lost all his aggressive traits, or they were in abeyance, he was amiable and, as a convalescent, occupied himself in ministering to the other patients in the ward.

Dr. L. A. SIMMONS thought that the depression at the apex of the fracture and the existence of a small clot did not point to such a change in the relations between the cranium and the contents as to constitute depression and compression. He would like to point out that the active processes had ceased soon after the accident. For some unknown reason certain cerebral symptoms had developed which were not those of late hæmorrhage or compression. The speaker did not believe that the depression of the temporal bone or the clot had caused sufficient compression to call for the operation; the operation had done the patient good, but not by relieving compression.

Dr. BRIDDON said that, as he had read the history, compression either by bone or by blood had not been regarded as the cause of the trouble. There were active inflammatory processes present for seven or eight days, as shown by the temperature of 105°.

**Vaginal Hysterectomy.**—Dr. A. J. McCOSH showed a woman, thirty-eight years of age, who had suffered from prolapsus uteri for eight years. He said his experience with plastic operations for this kind of trouble had been rather unsatisfactory. In this case he had decided that extirpation of the uterus was the best procedure. For some time the improvement had been marked, and no descent of the mass had occurred until a few weeks ago, four months after the operation. Now, however, the patient was in very much the same condition as before the operation, minus the uterus. The operation, so far as effecting a cure was concerned, had proved a complete failure. From his experience with four cases he had come to the conclusion that the ultimate results of this operation were far from satisfactory.

**Experience in the Treatment of Buboec by Excision and Injection** was the title of a paper read by Dr. McBURNEY.

Dr. BRIDGON thought that when the glands situated beneath the cribriform fascia were involved the dissection was difficult and there was always danger of injuring veins. He had twice divided the saphenous vein as it passed through the cribriform fascia to join the femoral vein and had been obliged to tie the femoral vein.

Dr. L. S. PILCHER said that he had looked with a good deal of skepticism upon the method of attacking large suppurating buboec with vaseline, and, indeed, no method of dealing with these conditions short of radical surgical methods had seemed to him worthy of acceptance. Evidence to the contrary had been given at this meeting and had come in such a way that it was impossible to refuse it credence. Some years ago he had made a series of observations on double buboec. On one side the gland was extirpated as a tumor and primary union sought for. On the other side the suppurating region was freely opened and eurented, the cavity packed, and secondary adhesions encouraged. The latter method had yielded the best results, and since that time he had used it as a rule.

Dr. STIMSON could confirm the statement as to the frequency with which only partial success followed excision of the inguinal glands. He had no experience of any accidents following the operation. He thought it best always to search at once for the femoral vein, and thus, by knowing where it was, be able to avoid it.

Dr. ROBERT ABBE said that the treatment with vaseline impressed him as a method to be tried. His own experience had been favorable after excision and packing for thirty-six hours and then allowing the edges of the wound to fall together and secure union. He had never sutured the skin over the incision made in getting out the glands.

Dr. WILLY MEYER said he always tried to first free the package of glands from all sides and then let the saphenous vein, where it entered the femoral, form the pedicle. He had invariably been able to do so. In two instances he had been obliged to leave a portion of the gland adherent to the vein, but no harm had resulted. He had in two cases of glandular abscess tapped with a large needle, and, after antiseptic irrigation of the cavity injected a ten-per-cent. solution of iodoform in ether. A perfect cure without the necessity of an additional cutting operation had ensued in both instances.

Dr. F. W. GWYER asked if Dr. McBurney had ever tried to prevent buboec by local treatment of the chaneroid. Success had followed the use, at Chambers Street Hospital, of salicylic acid spread thickly over the chaneroid. In one case in which a bubo had existed as a fluctuating tumor this treatment had resulted in the disappearance of the tumor.

Dr. McBURNEY said, as to accidents during excision of these glands, that none had occurred. Hæmorrhage from the vessels of the region could be attended to or prevented by previous ligation.

**Perforating Ulcer of the Bladder.**—Dr. WYETH reported the case of a man, aged forty-three, of good family history, who had always enjoyed robust health. For twelve years he had had a hernia which he said had always been reducible. He had had no injury. About twenty hours before his admission he had passed a large amount of bloody urine, but had had no pain in the bladder. Since then he had had constant pain in both shoulders, behind. There had been no other symptoms. He was admitted on November 17, 1891, at 1.30 p. m. He complained of nothing but pain in the back of the right shoulder. His temperature was 98°, his pulse good. He had a peculiar facies (intestinal). The abdomen was lax and not painful on pressure. He was given a warm bath, and passed a moderate amount of urine containing no blood. He was ordered fluid diet, also five grains of sodium benzoate every four hours. During the night he urinated twice, the amount passed being small. The urine was dark in color, of neutral reaction, and contained no albumin or sugar. At 8 a. m. on the 18th he complained of pain in and fullness of the bladder. A soft-rubber catheter was passed, withdrawing, first, clear urine and, finally, a little bloody urine. He had a loose stool. At 11 a. m. he was examined thoroughly. Rectal examination was negative. The abdomen was apparently normal. There was a large left inguinal hernia, doughy to the feel and not reducible. The stone-searcher passed easily into the bladder. The walls of the bladder were examined in all directions. The interior felt as if it contained about six ounces. The searching was done very carefully. Rugæ were distinctly felt. No pain followed the examination. The foot of the bed was elevated. At 6 p. m. four ounces of bloody urine were withdrawn. Pulse, 104 and good; respiration, 30; temperature, 99°. He had a stool, with no urine. Ordered suppositories of extract of opium, half a grain, and extract of belladonna, a quarter of a grain, one every four hours. At 8 p. m. he had a stool and vomited several times. At 4 a. m. on the 19th he was catheterized, and eighteen ounces were drawn, the first part clear, followed by a large amount of bloody urine. Pulse, 108; respiration, 30; temperature, 98°. The bladder was washed out with hot Thiersch's solution, four ounces at a time, three times. All the fluid seemed to return, and was bloody. An ice-bag was applied over the bladder. At 8.30 a. m. he vomited a green fluid. Pulse, 104; respiration, 30; temperature, 98°. His condition was about the same as on the day before. The abdomen was not distended. At 12 m. he was feeling badly, vomiting. A high enema was given, and caused a small movement. At 2 p. m. he was still vomiting a green fluid. Pulse, 116; respiration, 33; temperature, 100°. Five drops of Magendie's solution were given hypodermically. The abdomen was tense and tympanitic, and the hernia was tense. At 6 p. m. he had gradually grown worse. He had been stimulated freely by the rectum and hypodermically. Morphine had had but little effect upon the vomiting. At 4 p. m. thirteen ounces of urine were withdrawn with the catheter. At 9.15 p. m. he was anesthetized with chloroform and kelotomy was performed. The knuckle of intestine was found to be normal. The peritonæum was washed out with warm Thiersch's solution. The patient was freely stimulated during the operation, and reacted fairly well, but gradually collapsed during the night. He died early on the morning of the 20th.

At the autopsy the intestines were found loosely adherent. There was a small amount of bloody fluid in the abdominal cavity. The kidneys were normal. There was an opening between the cavity of the bladder and the free peritoneal cavity of about the size of half a dollar, with irregular, jagged edges. The adjacent part of the wall of the bladder was dark-colored.

**Injury of the Wrist.**—Dr. STIMSON showed a specimen taken from a man who had fallen from an electric-light pole

two days before. The injury was to the left wrist. There was dislocation together with an irregular form of fracture of the scaphoid bone. The injury had been produced by excessive dorsal flexion combined with some ulnar flexion. The semi-lunar bone had remained attached to the radius, and the scaphoid which joined it had been broken off by avulsion.

**Appendicitis.**—Dr. F. KAMMERER showed a perforated vermiform appendix that he had tied off on the third day of a perityphlitic attack. The patient, a boy of thirteen, when seen, had a very anxious expression and a temperature of 101°. The respiration and pulse were accelerated, and the abdomen was tympanitic, but the only symptom pointing to the affection on the right side was increased tenderness in the iliac region. After opening the peritoneal cavity by an incision along the external border of the rectus, the slightly adherent intestines were separated and the appendix was discovered lying behind and to the inner side of the caput coli. Around it there was a small collection of pus. After its removal the wound cavity was packed with iodoform gauze. The boy did well at first, although the temperature never was normal. Then the abdomen began to distend, occasional vomiting set in, and the patient died of septic poisoning on the seventh day. At the post-mortem no general peritonitis was found, but immediately adjoining the wound cavity, and separated from it by a thin wall of agglutinated gut only, was another collection of pus, about half a cupful, securely shut off from the rest of the peritoneal cavity by inflammatory adhesions. This, although lying in the true pelvis, had escaped detection by rectal palpation. Reviewing the case, the speaker thought this was one of those in which it was impossible to determine the course at the outset. He had assumed that a beginning general peritonitis was present, and had operated upon this indication, but the post-mortem examination had demonstrated that this was not so. Considering the difficulty in prognosticating perityphlitic attacks, the speaker did not believe that an absolute condemnation of exploratory puncture, as it had lately been uttered, was entirely justifiable. If all surgeons agreed that all cases of perityphlitis demanded surgical interference, then, of course, exploratory puncture would be a useless procedure. But this was not the case. As regarded the dangers attending puncture, the speaker was convinced that practically they did not exist. In the last few years he had frequently resorted to it, and had never seen an untoward symptom follow the use of the needle under the necessary precautions. The presence of pus was an absolute indication for operative interference, of whatever character that interference might be in the individual case. The speaker gave it as his conviction that the greater part of the cases that ended fatally did so from an extension of a localized inflammatory process to the general peritoneal cavity. This accident, he argued, could almost always be prevented by early operative interference. In conclusion, he now thought that in most cases exploratory puncture could be dispensed with, especially when the surgeon had determined to operate whether he drew out pus or not. But, where a small, deep-seated tumor was discovered in the iliac region during the first week of an attack, with no general symptoms except perhaps a rise of temperature, he confessed the withdrawal of pus was occasionally for him the signal to operate. To do away with all risk, the operation might follow puncture immediately.

Dr. McBURNEY said that, while not able to state directly from personal knowledge the dangers likely to accrue from the use of the exploratory needle in these cases, he quite believed that such dangers did exist and he objected to its use on theoretical grounds. A considerable number of cases called urgently for operation, such as those in which the vermiform appendix was already gangrenous and yet no pus existed. A great deal of harm could be done in such cases if the operator did not suc-

ceed in finding pus after a number of punctures and therefore deferred the operation.

*Meeting of December 9, 1891.*

The President, Dr. ARPAD G. GERSTER, in the Chair.

**Deformity of the Leg relieved by Fracture and Wiring.**

—Dr. R. F. WEIR presented a boy of six years who had had, three years previously, an extensive necrosis of the left tibia. An operation for its removal some six months later had resulted in a very loose false joint at the junction of the lower and middle thirds of the bone. This had caused the weight of the body in walking to be borne by bending at the false joint on the outer side of the foot and on the end of the fibula, which bone had hence become much bowed outward. When the limb was thus bent the shortening amounted to nearly three inches. The deformity was relieved by cutting away the false joint, which separated the tibial surfaces nearly an inch, and, after fracturing the fibula with a chisel, the broken ends of this latter bone were forced between the ends of the tibia and secured there by wiring. A good result had followed this procedure; the limb was now straight and firm, with a shortening of but three quarters of an inch.

**Nephrectomy for Nephrydrosis.**—Dr. WEIR also showed a patient, aged eleven, from whom he had removed a large multiple cystic or hydrotic kidney in May last. The boy had noticed for some six or seven months that the right side of his belly had gradually increased in size, and on examination it had been only with some difficulty that a flaccid tumor, apparently anterior to the kidney, could be made out. This had yielded, on lumbar aspiration, a clear fluid, free from urinary salts. An incision was made into the tumor from the loin by Dr. Bull, who thus ascertained it to be a nephrydrosis. No calculus was found, and, it might be stated, there had not at any time been a history of calculus formation. The sac was stitched to the skin and drained. The patient came under Dr. Weir's notice on May 1st. The discharge was quite purulent and very free, and the patient's general condition was deteriorating. Injection of water into the cavity showed it to be still very large, holding twenty-four ounces of fluid. It was determined to withdraw, if possible, as much of the thinned walls of the kidney as might be done, hoping that a certain portion of good kidney tissue would show itself and be saved with the ureter, in accordance with Tuffier's views of kidney regeneration. But, as the cyst walls were separated and withdrawn, which was easily accomplished by a T-shaped incision, it was seen to be a multiple distention of the whole kidney, of which only small scattered portions of the secreting tissues were left. The pedicle was a slight one and easily secured, and the tumor was removed. The ureter was seen to be occluded about an inch below the pelvis of the kidney, probably from a congenital cause. No calculus was found. Recovery was uninterrupted, but rendered tardy by the persistence of a sinus, which was so often due to a retained silk ligature. This had been the cause in this case. A curved probe had recently withdrawn such a retained portion of silk. The speaker had often found help in the extraction of such ligatures by the ordinary crochet-needle.

**Luxation of the Internal Meniscus.**—Dr. L. A. STIMSON showed a patient who had suffered from recurrent pain in and locking of the knee. The last attack had occurred about the middle of October, after immunity for six months, and had been caused by sudden outward rotation of the leg. The patient was completely disabled when seen by the speaker, the day after the last attack. There was inability to flex the knee more than 10°. Any attempt to go beyond this angle would give intense pain. On the inner side of the left knee could be

felt a firm mass occupying the anterior and outer aspect of the joint. The mass seemed to be cartilaginous, and gave the impression of a displacement of the internal meniscus. On cutting down, this was found to be the case. The detached anterior half of the cartilage was removed by division in front of its posterior attachment. The wound was closed and healing had been prompt. He showed the case because it was rare that active interference had been undertaken for such a condition.

Dr. WEIR said that there not infrequently existed rare troubles in the knee joint the nature of which could only be revealed by exploratory incision.

Dr. STIMSON said that in most of his cases an accurate diagnosis had been possible. One point was constant—namely, the movement of the leg by which the attack was provoked; it was partial flexion of the knee combined with outward rotation of the leg. Subluxation of the meniscus was now well recognized as a surgical fact, and deserved to be classed and spoken of by its appropriate title, to the exclusion of the term "internal derangement of the knee joint."

**Excision of the Elbow Joint.**—Dr. F. LANGE presented a patient on whom he had performed excision of the elbow joint seven weeks before. He presented the case to illustrate his technique and after-treatment. Otherwise the case did not present any extraordinary features. The process had gradually developed within two years, and was tuberculous osteitis. The speaker had made three incisions—one main incision on the posterior aspect over the inner side of the olecranon as usual, but, besides that, two lateral incisions over the epicondyles, and downward, and this in order to get an easy access to those important points where the strong ligamentous and tendinous attachments of the joint normally existed, which, according to a proposition of Professor Veit's, of Greifswald, were left in connection with a thin shell of bone, which was chiseled off the cortical substance. The same was done on the attachment of the triceps. The after-treatment was by loose tamponade of the joint, and drainage through the wound over the internal epicondyle, but at the end of the second week everything was allowed to close, no purulent secretion being then present. About four or five weeks after the operation the patient got an apparatus which he still used. It fulfilled the following indications: First, by its being suspended from the shoulder to lift the forearm, so that its weight would not exert traction on the new joint; second, to keep the elbow at a right angle by elastic straps. The muscular action was done by the patient's holding weights in his hand just heavy enough to pull the hand slowly down. Against the force of this weight his flexor muscles had to battle. Extension was practiced without a weight against the action of the elastic straps. Third, to bring the bones at the new elbow into such relation to each other that those of the forearm were slightly pushed behind that of the arm. In this way the physiological conditions of the elbow joint were imitated. The splints were jointed with each other in such a way that they would allow of a certain amount of slipping of the forearm in an upward direction, and of their being pressed against those of the arm through a lever action, the point of support being transferred to the points of attachment of the elastic straps. The functional result was a very good one already. Even without the apparatus the movements were already safe and fairly strong. The patient could, in lateral elevation and pronation, make extensive excursions in the elbow joint. There would certainly not be a flail-joint as the result. There was a distinct new formation of bone at the points where the soft parts had been chiseled off. The patient's general condition had become excellent.

**Excision of a Large Ulcer of the Stomach; Adenoma.**—

Dr. LANGE also presented a butcher, twenty-five years of age,

who had begun to have pain in the region of his stomach about two years before. The pain was mostly located in the middle, sometimes more to the right or the left, and often radiating into the back. It would mostly come on when the stomach was empty, and was relieved by taking food, especially liquids, also often by the recumbent posture. He had vomited only twice during his illness and never discharged blood by the mouth or with his stools. He had been treated for various things—enlargement of the liver, gastric catarrh, rheumatic affection, neuralgia, and finally supposed ulcer of the stomach. This last treatment was maintained for several months, from the beginning of April to the beginning of June of this year, but with no benefit at all. In July the patient was examined under chloroform anaesthesia, and a descended kidney was assumed as the probable cause of the trouble by another surgeon. The speaker had seen him at about the end of September. By palpation nothing certain could be made out, and, the patient's suffering being very intense, probatory laparotomy was proposed. Owing to the absence of dilatation of the stomach or any symptoms pointing to the presence of an ulcer, the speaker had been inclined to assume the gall-bladder as the seat of the trouble, especially since on deep pressure that region had seemed to be painful. On the 26th of October laparotomy was done. A longitudinal incision was made over the gall-bladder. The latter was found in healthy condition. Adhesions over the duodenum, which seemed to compress it, were cut across. On passing the hand toward the middle line, a hard disc could be felt on the anterior wall of the stomach. A cross-incision to the middle line was made at a right angle to the upper part of the existing opening. The mass, which felt like a cancerous tumor, was pulled forward. The omentum was tightly adherent. The hard disc and a good deal of the apparently healthy neighborhood were excised. It measured from four to five inches in diameter, of which the ulcer itself occupied a central area about three inches in diameter. The bottom of the central portion was formed by omentum and was of about the size of a five-cent piece; the wall of the stomach seemed to be entirely gone. The edges of the ulcer were sharp and abrupt. The stomach wall in the neighborhood was much thickened, but microscopically did not appear like a carcinoma. Several glands of the omentum were removed. The opening in the stomach was enormous after the cicatricial traction of its walls had ceased. At one point less than half of the circumference remained, since here the operation had had to be extended beyond the insertion of the omentum. To prevent narrowing at this point the large wound was united partly in a longitudinal direction on the upper edge, as well as on the lower. The main line of suturing was from the left to the right, and the whole line of suturing formed an irregular cross. The inner row of sutures was done with iodoform catgut, the outer with silk thread. On the points of crossing additional sutures were placed. A loose iodoform-gauze packing was used over the lines of suture and at the point where the two abdominal sections met. The operation lasted almost four hours. In spite of that, the patient was in fairly good condition. He had lost considerable blood from the wound in the stomach, where numerous vessels had had to be tied, and several injections of wine and water were given during and after the operation. There was continuous vomiting during the first four days, with moderate elevation of temperature. The patient was given enemata alone for about a week, during the second week with small quantities taken by the mouth. From the end of the third week all food was taken through the mouth. The patient was kept in bed four weeks and discharged two days later. His pain had not recurred since the operation, and he was gaining strength rapidly. The microscopical examination made it probable that the tumor was an adenoma the center of which was ulcerated and digested, while

the peripheral part showed luxuriant adenomatous formations and much chronic inflammatory infiltration.

**Fracture of the Base of the Skull; Cerebral Hæmorrhage; Death.**—Dr. BRIDGES reported the case of a man, fifty-five years old, who had been admitted into the Presbyterian Hospital on November 19th. Family history negative. While under the influence of liquor, he had fallen from a stairway a distance of about eight or ten feet, landing upon the hard pavement and presumably striking on the left side of the head, from the existence there of a slight abrasion and a small hæmatoma. On his admission he was in a mild degree of alcoholic stupor, combined with concussion. His temperature was 97°, his pulse 70, and his respiration 17. His face was flushed, and his pupils were contracted but equal. From the left ear there was a slight bloody discharge. Over the left parietal boss there was a small abrasion of the skin with a contused area about two inches in diameter, but no evidence of depression or fracture could be detected. Physical examination of the thoracic and abdominal organs revealed nothing pathological, except that the liver was somewhat diminished in size. There was slight œdema of the extremities. There was no paralysis. The head was shaved, an ice-cap was applied, and ten grains of calomel were administered. During the night and the following day the patient was very restless and at times delirious. Some slight nervous twitchings on the left side of face were noticed, but no other facial symptoms were observed. On account of the bloody discharge from the left external auditory meatus, which ceased at the end of thirty-six hours, the ear was carefully cleansed, dusted with boric acid, and treated with the strictest antiseptic precautions. On the third day the delirium still continued and the temperature rose to 102°, the pulse being 76, and the respiration 20. On the following day (four days after the accident) his mental condition became more sluggish and stupid, and only with difficulty could he be aroused. Convulsive seizures were now first noticed. There were spasmodic twitchings of the left side of the face, and of the left arm and leg, and violent clonic muscular contractions of the right arm. The optic axes deviated decidedly to the left. The pupils were dilated, but equal. The pulse was slow, full, and bounding. During the interval between the convulsions there was paralysis of the left arm and leg, and the patient lapsed into a semi-comatose condition. In the next twenty-four hours there were sixteen seizures similar to those described, each lasting about two minutes. On the following day the temperature fell to normal, the pulse to 60, and the respiration to 16. The functions of the left arm and leg were restored and the patient rested quietly. There were now noticed some slight ecchymosis and bagginess over the mastoid process of the left side. During the following week there were no further convulsions, there was no rise of temperature, and the mental condition became much improved. Examination of the urine now showed seven per cent. of albumin and a few hyaline and granular casts. On the morning of the 30th there was noticed a marked inequality in the pupils, the right being the larger. This condition lasted, however, only twelve hours. On December 3d, two weeks after his admission, the temperature rose to 101.5°, the pulse to 118, and the respiration to 28, and he rapidly grew weaker and more stupid. The urine and faces were passed involuntarily. On the next day there was a rapid rise of temperature, until at 11 p. m. it had reached 106.5°, the pulse being 146 and the respiration 40. Death occurred two hours later. At the autopsy a fracture was found extending from a point about half an inch below and behind the left parietal eminence, through both plates of the skull, to the external auditory meatus. Inside, it ran along the upper surface of the petrous bone, about an eighth of an inch in front of the edge. The fracture lay close in front of the membrana tympani, but did not involve it.

There was evidence of there having been profuse hæmorrhage beneath the dura, all over the convexity of the right hemisphere. The clots were in part intimately adherent to the dura. The brain was otherwise normal. In the lungs there were found a few old adhesions, some fibrous nodules on the surface, much congestion, and abundant mucopus in the bronchi. The kidneys were somewhat congested, the cortex was slightly opaque, and the capsule was adherent. The remaining abdominal organs and the heart were normal.

## Book Notices.

*Practical Midwifery: A Hand-book of Treatment.* By EDWARD REYNOLDS, M. D., Fellow of the American Gynecological Society, etc. With One Hundred and Twenty-one Illustrations. New York: William Wood & Company, 1892. Pp. xiv + 421.

This book, though intended for the medical student, contains many practical hints which might be of service not alone to the "busy practitioner," for whom so much is nowadays done, but to the every-day practitioner whose cases do not come so frequently that his knowledge is at his fingers' ends. Although as a rule the author steers a safe middle course, and hence is a safe guide, there are not a few points which call for criticism: for instance, the advice to make frequent examinations in the first stage of labor, to ascertain the exact position of the head, and in the second stage to ascertain the advance it is making. Another instance is the freedom with which injections of bichloride of mercury (1 to 3,000 and 1 to 4,000) are recommended. We are surprised to find that no mention is made of tamponing the uterus with iodoform gauze in cases of severe post-partum hæmorrhage. We think that, considering the importance of the matter, greater space might have been allotted to the subject of septicæmia. Apart from these criticisms, the book can be very warmly recommended to the class for whom it was written.

*Hospice de la Salpêtrière. Clinique des maladies du système nerveux.* M. le Professeur CHARCOT. Leçons du professeur, mémoires, notes et observations. Parus pendant les années 1889-'90 et 1890-'91, et publiés sous la direction de GEORGES GILNON, chef de clinique. Avec la collaboration de MM. HALLION, DE LA TOURETTE, BLOCC, HUET, PARMENTIER, SOUQUES, HALLION, J. B. CHARCOT et MEIGE, anciens chef de clinique, internes et interne provisoire de la clinique. Avec 47 figures et 3 planches. Paris: Veuve Babe et cie., 1892. [Publications du *Progrès médical*.] Pp. iii+468. [Prix, 12 francs.]

This is the first volume of a collection of the lectures, observations, notes, and original researches made by Professor Charcot and his pupils, and published in various journals between 1889 and 1891. The original publications are not always accessible; and to those who are interested in neuropathology this plan of reuniting scattered essays will be particularly convenient.

In the present volume are lectures on Morvan's disease, hystero-traumatism, hysterical tremor, ophthalmoplegic migraine, blue œdema in hysterical subjects, amyotrophic paralysis in the popliteal region, external ophthalmoplegia, diabetic paralysis, hysteria in the male, the gait in hemiplegics, cerebral syphilis, and abortive types of sclerosis in patches, together with a contribution to the study of hysterical yawning. Many of these papers have been noticed in the *Journal* in the reports on the progress of medicine and of neurology.

The volume is an interesting one, and will undoubtedly prove to be of great convenience for reference.

BOOKS, ETC., RECEIVED.

A Text-book of the Practice of Medicine for the Use of Students and Practitioners. By R. C. M. Page, M. D., Professor of General Medicine and Diseases of the Chest in the New York Polyclinic; Visiting Physician to Raudall's Island Hospital, etc. New York: William Wood & Company, 1892. Pp. x to 568.

Text-book of the Eruptive and Continued Fevers. By John William Moore, B. A., M. D., M. Ch., Univ. Dubl., Physician to the Meath Hospital, Dublin, etc. William Wood & Company, 1892. Pp. xxv to 535.

Maladies des voies urinaires: urètre—vessie. Exploration, traitements d'urgence. Par P. Bazy, chirurgien des hôpitaux de Paris. Paris: G. Masson, 1892. Pp. 7 to 187. [*Encyclopédie scientifique des aide-mémoire.*]

Technique bactériologique. Par le Dr. R. Wurtz, chef du laboratoire de pathologie expérimentale à la Faculté de médecine de Paris. Paris: G. Masson, 1892. Pp. 9 to 192. [*Encyclopédie scientifique des aide-mémoire.*]

Diseases of the Nervous System. By J. A. Ormerod, M. D., etc., Medical Registrar and Demonstrator of Morbid Anatomy at St. Bartholomew's Hospital, etc. With Numerous Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. xiv-13 to 343.

On the Choice of Operation for Removal of Stone from the Bladder. By L. Bolton Bangs, M. D. [Reprinted from the *Annals of Surgery.*]

A Peculiar Accident during Litholapaxy. By L. Bolton Bangs, M. D. [Reprinted from the *Maryland Medical Journal.*]

Four Cases of Orbital Traumatism resulting in Immediate Monocular Blindness through Fracture into the Foramen Opticum. In One of these Cases the Blow was over the Left Orbit, causing blinding of the Right Eye. By Peter Callan, M. D., New York. [Reprinted from the *Journal of the American Medical Association.*]

The Science and Art of Midwifery. By William Thompson Lusk, M. D., Professor of Obstetrics and the Diseases of Women and Children in the Bellevue Hospital Medical College, Consulting Physician to the Maternity Hospital and to the Foundling Asylum, etc. New Edition, revised and enlarged, with Numerous Illustrations. New York: D. Appleton & Co., 1892. Pp. xviii to 761.

The Electro-therapeutics of Gynaecology. By A. H. Golet, M. D., Fellow of the New York Academy of Medicine and of the New York Obstetrical Society, etc. Part I and Part II. With Illustrations. Detroit: George S. Davis, 1892. [The *Physicians' Leisure Library.*]

History of the College of Physicians and Surgeons in the City of New York; Medical Department of Columbia College. By John C. Dalton, M. D., President, and Professor Emeritus of Physiology. Published by order of the College, 1888.

Trattato d'igiene pubblica. Del Dottor Carlo Ruata, Professore dell'Università di Perugia. Vol. I (parte generale). Castello: S. Lapi, 1892. Pp. x to 271.

De l'influence du courant continu sur les microbes, et particulièrement sur la bactériologie charbonneuse. Par MM. Apostoli et Laguerrière. [Extrait du *Répertoire de police sanitaire, vétérinaire et d'hygiène publique.*]

Studies upon Injuries of the Kidney, Nephrolithotomy, and Nephrorrhaphy. By Aug. Schraclmer, M. D. [Reprinted from the *Annals of Surgery.*]

Eleventh Annual Report of the State Board of Health of Illinois. Being for the Year ending December 31, 1888. With an Appendix containing the Official Register of Physicians and Midwives, 1892.

Presbyterian Hospital in the City of New York. Twenty-third Annual Report, 1891.

Thirty-first Annual Report of the Cincinnati Hospital to the Mayor of Cincinnati, for the Year ending December 31, 1891.

## Miscellany.

The Association of American Physicians will hold its seventh annual meeting in the Army Medical Museum and Library Building, Washington, on Tuesday, Wednesday, and Thursday, May 24th, 25th, and 26th, under the presidency of Dr. Henry M. Lyman, of Chicago. Besides the president's address, the programme gives the following titles: The Cold-water Treatment of Typhoid Fever, by Dr. G. Wilkins, of Montreal; The Treatment of Follicular Tonsillitis, by Dr. G. M. Garland, of Boston; A Collective Investigation in Regard to the Value of Quinine in Malarial Hæmaturia or Malarial Hemoglobinuria, by Dr. H. A. Hare, of Philadelphia; Alcoholism, by Dr. T. S. Latimer, of Baltimore; Practical Results of Bacteriological Researches, by Dr. G. M. Sternberg, of the navy; The Treatment of Experimental Tuberculosis by Koch's Tuberculin, Hunter's Modifications, and other Products of the Tubercle Bacilli, by Dr. E. L. Trudeau, of Saranac Lake, N. Y.; Report of a Case of Glanders, with Results of Bacteriological Study, by Dr. William Pepper, of Philadelphia; The Bacteriological Study of Drinking Water, by Dr. V. C. Vaughan, of Ann Arbor, Mich.; The Morbid Anatomy of Leprosy, by Dr. Heneage Gibbes, of Ann Arbor, Mich.; Discussion on Dysentery (Etiology and Pathology, by Dr. W. T. Councilman, of Baltimore; Symptomatology, Complications, and Treatment, by Dr. A. B. Ball, of New York); The Treatment of Acute Dysentery by Antiseptic Colon and Rectal Irrigation, by Dr. W. W. Johnston, of Washington; A Contribution to the Study of Hepatic Abscess, by Dr. W. C. Dabney, of Virginia; Pulsating Pleural Effusions, by Dr. James C. Wilson, of Philadelphia; A Case presenting the Symptoms of Landry's Paralysis, with Recovery, by Dr. F. T. Miles, of Baltimore; A Case showing Symptoms of Landry's Paralysis—Recovery, by Dr. A. McPhedran, of Toronto, Canada; The Areas of Anæsthesia in Spinal-cord Lesions as a Guide to Localization, by Dr. M. A. Starr, of New York; A Study of the Seasonal Relations of Chorea and Rheumatism for a Period of Fifteen Years, by Dr. Morris J. Points in Uterine Therapeutics.—We are indebted to the *Occidental Medical Times*, of Sacramento, for proof-sheets of its excellent report of the recent meeting of the Medical Society of the State of California. Among the proceedings we find an interesting communication on The Septic Origin and Antiseptic Treatment of Chronic Endometritis, by Dr. W. A. Briggs, of Sacramento, the chairman of the committee on gynecology, in the course of which he says: In my earlier gynecological

work, tincture of iodine was quite in vogue and gave me many a *man-vais quart d'heure* in my office. Repeated experiences with uterine colic diminished my zeal as well as that of my patients for this form of treatment. The monotonous futility of the applicator, however, drove me to the resumption of injections, with the previous result. Notwithstanding this unpleasant and unsatisfactory experience, I have latterly resumed intra-uterine injections, although in somewhat different form, with different purposes, and invested with greater precautions. I use them now as but one element of a systematic and consistent whole—the antiseptic treatment; and, I feel sure, with better results, immediate as well as remote.

After considerable experimentation, I have found that camphor-creasote is an excellent solvent for iodine, and, over alcohol, possesses the following advantages: (1) It does not coagulate albumin. (2) Being thick and oily and having no affinity for water, it does not come in such rapid contact with the mucous surface, and hence is not so likely to produce severe pain. (3) It dissolves by far the largest ratio of iodine of any liquid with which I am acquainted—roughly estimated, about twenty-five or thirty per cent. by weight—and hence can be used in a correspondingly smaller quantity, and with marked immunity from uterine colic. Occasionally, it must be confessed, it will provoke considerable pain and even colic, but I believe much less frequently than tincture of iodine, and, if properly used, very rarely.

The formula is as follows:

R̄	Camphoræ.....	gm. 16;
	Creasoti fagi silvat.....	c. c. 6.
	M. solve et adde	
	Iodini resub.....	gm. 7.

If the orifice is not patulous enough to permit the ready outflow of the injection it should be sufficiently dilated by Hegar's bougies. For these injections I take a deep urethral syringe, with small terminal and lateral perforations, wrap the last three inches of the nozzle with a thin layer of absorbent cotton, dip it in the iodized camphor-creasote, pass it quickly through the cervix to the fundus, and, expressing two or three minims of the solution at a time, spread it thoroughly over the entire mucosa. During this process careful watch should be kept to see if the injection escapes freely, and, if not, the cause should be ascertained and removed before proceeding further. Injections should be limited to ten or fifteen minims, and repeated every second or third day, and, as improvement manifests itself, every fifth or seventh day.

Having made the injection, we are now prepared for cataphoresis, which is done by introducing into the uterus a platinum electrode, whose active surface corresponds in length with the uterine cavity and constitutes the positive pole of the utero-abdominal current, varying from five to twenty milliamperes. The electrode is covered with absorbent cotton, saturated with iodized camphor-creasote, and made to sweep the mucosa in its entire extent, not neglecting the cornua. The sitting lasts from five to ten minutes and is repeated with each injection. If the case be a hæmorrhagic one of recent origin, the current is raised to thirty, forty, or even fifty milliamperes, and the application repeated if necessary weekly during one or two intermenstrual periods. The uterine mucosa is capable of active absorption, and under the influence of electricity we may introduce considerable quantities of iodine or other remedy into the general circulation. This fact may be of importance in uterine cataphoresis. After treatment, patients will often complain of a metallic taste before leaving the office, and sometimes before leaving the gynæcological chair.

In the algæic form of endometritis the positive pole produces sedative effects that render it doubly valuable. Pain will be often markedly relieved by three or four applications. Whenever the uterine cavity is enlarged and the uterine tissue flabby, it will be advantageous to combine the faradaic current with the galvanic, which is easily done by means of double cords terminating in single electrodes, to continue it for ten minutes, and repeat it every second day. This treatment is of marked benefit, not only in the relief of pain, but also in the promotion of uterine circulation and the absorption of inflammatory exudates.

In confirmed hæmorrhagic and hypertrophic endometritis it is difficult, if not impossible, to restore the diseased mucosa to its normal condition; nothing less than its destruction will produce a satisfactory result. For this purpose we have several means at command—chemical

cauterization, positive galvano-chemical cauterization, and eurette. Nitric acid and chloride of zinc are undoubtedly efficient, but it is impossible to limit their action to the diseased structures, and so often do they entail cicatrices, stenosis, and sterility that their use is altogether indefensible. The same objections perhaps, although in a far inferior degree, apply to galvano-chemical cauterization. But in recent cases, or in inveterate ones, in which the patient will not consent to its use, we have in positive galvano-chemical cauterization a sovereign remedy, which, if used by the antiseptic method, is altogether free from danger. By the cataphoric action of the positive pole the eschar becomes aseptic from absorption of iodine, and, in my experience, breaks down and passes away without the slightest untoward result. Besides, the acids generated at the positive pole are themselves more or less antiseptic and assist in the general effect. For the purpose of a cauterant, the current should vary from thirty to sixty milliamperes, and be maintained from five to eight minutes in weekly sittings. With the large currents recommended by Apostoli I have had no experience in endometritis, but I must confess to a prejudice against them, which must be overcome, if overcome at all, by positive and indisputable evidence of their freedom from untoward secondary effects.

Curetteage, however, I prefer. My own experience leads me to concur in the opinion that, properly done in properly selected cases, it is one of the safest and not the least efficient of surgical procedures. In hæmorrhagic and hypertrophic endometritis the uterine mucosa is soft and pulpy, and, moreover, it is an essential feature of curettage that it leaves the terminal *culs-de-sac* of the mucous glands as a basis for the regeneration of the membrane. The sharp curette of Sims, therefore, and the cutting spoon of Simon, are out of place in this condition, and I habitually employ the irrigating curette with an edge, as Pozzi says, like that of an unfiled knife-blade. The irrigating current should be turned on from a reservoir with a head not exceeding eighteen or twenty inches. A bulb syringe should never be used, for it is difficult accurately to estimate the force exerted on the bulb, and the intra-uterine pressure is liable to be raised to a dangerous degree. The curettage should be systematic and thorough, especially in the neighborhood of the tubal orifices. The irrigation should continue until the *débris* has been completely removed and the fluid returns nearly or quite colorless. The curette should then be withdrawn, and ten or fifteen minims of iodized camphor-creasote should be introduced into the uterus by the syringe-applicator and spread over the entire denuded surface.

Drainage is the next, and an important element of the antiseptic treatment. In a large majority of the serious and annoying cases of endometritis coming under my observation the uterus has been either retroverted or retroflexed, or both retroverted and retroflexed. These backward displacements are probably partly cause and partly consequence of the inveteracy of the inflammatory condition. In the first place, they prevent drainage, especially in the recumbent position. The secretions stagnate, microbes multiply and maintain a constant irritation of the endometrium. In the second place, they hinder the uterine circulation, produce stasis and malnutrition, and thus furnish conditions extremely favorable to the development and maintenance of inflammation. Such displacements, therefore, if possible, should be corrected early in the course of treatment, and reposition, if necessary, be maintained by antiseptic cotton or lamb's-wool pessary. Artificial drainage, I believe, is frequently advantageous and occasionally necessary. Iodized candle-wicking, which is prepared by immersing the wicking in tincture of iodine and drying it without heat, seems to me to answer a better purpose than iodoform gauze. It should be introduced well within the uterine cavity and be supported by an antiseptic tampon.

The uterine treatment, whether of injection and cataphoresis or of curettage, having been completed for the day, we reach the question of vaginal dressing, which, while always antiseptic, will be determined in a measure by our views of the necessity or advantage of local depletion. As nearly every patient suffering with chronic endometritis becomes more or less anæmic, blood waste in every form, even the menstrual flow, should be restricted rather than promoted. For this reason, and because I rarely witnessed any improvement even in the local condition from the application of either the natural or the artificial leech, I long ago altogether discarded local bloodletting. But glycerin, by its high specific gravity and affinity for water, as well as various hygroscopic

powders, produce a free exosmosis from the engorged vessels, and thus effectually deplete them without impoverishing the blood. They also serve another useful purpose: By distending the vagina and inviting the effusion of considerable quantities of liquid, secretions and microbes, if unfortunately they escape all our previous precautions, are rapidly carried out of the body. Tampons of glycerole of tannin possess other advantages—they leave an astringent after-effect, which, in accordance with the law of diffusion of liquids, extends well into the cervical canal and probably into the uterine cavity itself; they support the uterus in ease of displacement, and thus promote drainage, the uterine circulation, and the absorption of inflammatory exudates. The vaginal dressing, therefore, by promoting antiseptics, drainage, the uterine circulation, and the depletion, with subsequent contraction of the engorged uterine vessels, is an indispensable element of the antiseptic treatment.

Should the support of a tampon be unnecessary, and the astringent effect of the tannin undesirable, or should there be vaginal leucorrhœa, dry packing with boric acid and sulphur (9 to 1) will be an excellent substitute. This dressing, whether of liquid or of powder, will produce considerable discharge from the vagina. A napkin, therefore, is necessary, for the purpose of cleanliness as well as to furnish the final element of the antiseptic treatment. It should be made of antiseptic gauze, woru constantly, and changed twice daily, after the vaginal injections.

**An Act to Regulate the Practice of Midwifery in the State of New Jersey** was approved on March 28th. The text is as follows:

1. Be it enacted by the Senate and General Assembly of the State of New Jersey, That every person practicing midwifery in any of its branches shall possess a certificate from the State Board of Medical Examiners as hereinafter provided.

2. And be it enacted, That every person now practicing midwifery in cities of the first and second classes in this State shall, within thirty days after the passing of this act, personally present to the State board of medical examiners an affidavit setting forth the name, nationality, age, authority, location, and length of practice, together with a certificate of good moral character from some registered physician, resident of the same district; whereupon the board, on receipt of a fee of one dollar, shall issue a certificate, signed by its president and secretary and bearing the seal of said board, entitling the person named therein to practice midwifery in this State.

3. And be it enacted, That every person hereafter beginning the practice of midwifery in this State shall appear before the State board of medical examiners and submit to such examinations in midwifery as the board shall require, and if such examination is satisfactory to the examiners, the said board shall, upon the receipt of a fee of five dollars, issue a certificate the same as provided in section two of this act.

4. And be it enacted, That the person so receiving said certificate shall file the same or a true copy thereof with the clerk of the county in which she resides, and said clerk shall file said certificate or a copy thereof, and enter a memorandum thereof, giving the date of said certificate and the name of the person to whom the same is issued, and the date of said filing, in a book to be provided and kept for that purpose; and for which registry the said county clerk shall be entitled to demand and receive from each person registering the sum of twenty-five cents.

5. And be it enacted, That the State board of medical examiners are hereby authorized and empowered to execute the provisions of this act, and shall hold examinations of candidates for certificates in midwifery at such times and places as may be deemed expedient.

6. And be it enacted, That the State board of medical examiners may refuse licenses to persons guilty of unprofessional or dishonorable conduct, and may revoke licenses for like cause, or for neglect to make proper returns to the various health officers, of births, and the cases of puerperal and other contagious diseases occurring in their practice.

7. And be it enacted, That any person shall be regarded as practicing midwifery within the meaning of this act who shall publicly profess by advertisement, sign, card, or otherwise to be a midwife, or who shall, for a fee, attend to women in childbirth; but nothing in this act shall be construed to prohibit gratuitous service in case of emergency, nor to the legally qualified physicians or surgeons of this State.

8. And be it enacted, That any person practicing midwifery in this

State without first complying with the provisions of this act, shall be guilty of a misdemeanor and shall be punished by a fine of not less than ten dollars nor more than fifty dollars, or by imprisonment in the county jail for not less than ten nor more than thirty days, or both, in the discretion of the Court.

9. And be it enacted, That all acts or parts of acts inconsistent herewith be and the same are hereby repealed, and that this act shall take effect immediately.

**The New York Academy of Medicine.**—The special order for the meeting of Thursday evening, the 19th inst., was a discussion on The Causes and Treatment of Endometritis, opened by Dr. W. R. Pryor.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 25th inst., Dr. J. E. Newcomb will report a case of Adenocarcinoma of the Fauces, Dr. J. W. Wright will present a case of Carcinoma at the Base of the Tongue, and Dr. J. E. Nichols will read a paper on Disease of the Frontal Sinus.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, the 26th inst., Dr. C. A. von Ramdohr will read a paper on The Treatment of Puerperal Fever, and Dr. F. Krug will read A Report of Some Interesting Cases of Extra-uterine Pregnancy.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

## Original Communications.

SOME SURGERY OF  
THE LIVER AND GALL-BLADDER.\*By J. C. REEVE, JR., M. D.,  
DAYTON, OHIO.

THESE organs dispute only with the intrameningeal and intestinal tissues the claim of being the latest regions to be invaded by our art. Their surgery, though differing in no general way from other surgery, or rather in no particular way from other abdominal surgery, requires, nevertheless, in its more difficult features, a greater command of technique than that of any other part of the body. The making of delicate seams in the ducts, lying as they do deep in the abdomen and at times almost out of reach, must often be difficult beyond accomplishment. But the object of this paper being the practical presentation of some points, and its form but the hasty collection of actual material, we will pass at once to the consideration of some cases.

*Abscess of the Liver.*—Fullness in the hypochondrium and difficulty in lying on the right side, pain in the right shoulder, dyspepsia, nausea, vomiting, rigors, fever, sweating, irritability of the nervous system, cough, local enlargement, dysentery, jaundice rarely—these make up the complete picture of this trouble; but that it is often announced by much fewer symptoms is not necessary to state—in fact, can exist without manifestation until another cause brings the subject to the dead-room. In order of frequency, these may be placed in this sequence: First, digestive disturbances; second, pain; third, fever; while jaundice is so rare as to weigh rather against than for abscess. The fever, with its chills, sweats, and intermissions, so like that from malarial cause, is often mistaken for it. The following will fairly represent the subject in hand:

CASE I.—A strong German, fifty-eight years of age, and a stone-cutter, had been complaining of pain in the abdomen and slight diarrhoea for several months before entering the hospital. His temperature was then fluctuating between 99° and 101°, with the higher figure usually in the evening. The pain was in the liver region, but whether extending to the shoulder we are unable, after several years, to recollect. The diarrhoea was considerable and not lessened by the usual remedies; the stools were thin, but not lacking color. It was not long after his admission until increase in liver dullness appeared, and the diagnosis of abscess was made and an operation suggested; but, as this diagnosis was not supported at a consultation, the case was continued tentatively. At the beginning of the fifth week of observation the temperature was from 101° to 103°, and all the man's symptoms were worse. Besides, he had chills, vomiting, much sweating, and, on the thirty-ninth day of this record, coughing began. On the next day a very long coughing spell. On the forty-fourth day it was plainly demonstrated at a consultation held that day that the upper line of liver dullness was rapidly rising. (That it was the liver and not pleuritic dullness was told by the method of percussing the highest line of dullness during expiration and then seeing that it disappeared upon

full inspiration.) A few days later widespread pain, and on the fiftieth day a circumscribed flush on the most prominent part of the distention that occupied the upper right part of the abdomen—in fact, all the conditions which Greig Smith calls “signs of the abscess bursting of its own accord,” and he adds: “Redness, tenderness, and some swelling at any point over a hepatic tumor, which is probably suppurating, may be taken as an indication that the matter is forcing its way to the surface. In such cases there will be adhesions between the liver and the overlying peritonæum, and an opening may be made with safety. It need scarcely be said that such a tendency to point is neither to be waited for nor encouraged, . . . and before the signs of pointing appear the patient will have been reduced to a very low ebb.” But it was not until two days later, four weeks after the diagnosis was first made, that agreement with a consultant was reached as to the need of evacuation, and aspiration was the means fixed upon.

And here we may consider the several surgical methods of dealing with abscess of the liver, for medical there are none.

First, aspiration. It has the disadvantage of uncertainty in finding a small collection of matter, and, in common with its use in all abscesses, the impossibility of removing all material. The later exclusion of air is almost sure to fail, and hence the conditions for hectic are perfect—the accession of the atmosphere to retained pus. Further, the danger of leakage into the peritoneal cavity is great. Puncture by trocar has the same disadvantages, except adhesions are known to exist, when danger of leakage is absent. Opening by caustics is bungling and inhuman, and by thermo-cautery of application only in late stages. Opening by “direct incision” would be attempted only when pointing, as above described, existed, and “by incision in two stages” only when ample time was to be had. The latter operation consists in incising the parietes to the peritonæum, packing the wound in order to excite enough inflammation to cause the viscus to adhere to the parietal fold, and, a few days later, incising the liver through the peritonæum. Finally, there is hepatotomy—that is, by means of laparotomy. Here we have the advantage of sight, possibly, in detecting the position of the abscess, in detecting other abscesses, and in avoiding omentum and bowel, which might have suffered in the making of puncture or adhesions, and the advantage of protecting the peritoneal cavity. Though some choice of these means lies certainly in the demands of the case, it is to the last we must look for best results, and it has already given us these in the hands of such operators as Tait and others. The incision is over the most prominent part of the tumor, four or five inches long. If in exploration suitable adhesions are found to exist, the collection is punctured through the parietes by a large trocar. If not, the abscess is incised, and its edges stitched to the parietes. This is much easier if the case is from a suppurating hydatid cyst, because there is then a distinct limiting membrane. Several operators have presented in late numbers of the *British Medical Journal* their methods of aspiration, and with most siphon drainage to the floor is adopted. With this and several other details this operation has not all of the above disadvantages, and that it is efficient the results of these gentlemen show.

\* Being parts of a paper read, with specimens, temperature charts, and diagrams, before the Montgomery County, Ohio, Medical Society.

But to return to our patient. His tumor was aspirated at the point of most prominence in the right hypochondrium, and several quarts of grumous pus obtained—grumous from shreds of liver tissue. The tube was not withdrawn for four days, during which time large quantities of pus continued to flow, with no improvement, however, in his condition, except that the pain had disappeared. When the needle was withdrawn, the matter continued to discharge four days longer, when the patient died from exhaustion. To-day we would refuse to treat this case except by free incision, and in its earlier stages except by laparotomy.

*Tumors of the Liver.*—From its extreme vascularity and friability, no tissue in the body has the surgeon attacked with more trepidation than that of the liver. Yet every week brings new accounts of neoplasms removed from its embrace, and even portions of the organ excised. The frightfully abundant hæmorrhage from its cut surface can, however, be checked—usually by the cautery, but often, in meeting the larger vessels, the ligature itself must be applied, a procedure which certainly must be difficult and unsatisfactory from the above features of the liver substance. Even lesser means will suffice, as will be seen by an instance below.

*Cholelithiasis.*—Though usually very easy of diagnosis, the presence of gall-stones is at times so unsuspected that we tarry only long enough on diagnosis to present two cases in point. They were mentioned to the society last winter, but we venture to report them fuller. At that meeting a member read a paper on gall-stone colic and the favorable results he had had from phosphate of sodium, a remedy which, together with olive oil, we do not reject. But the results were so favorable that we ventured to doubt to some extent the diagnoses.

CASE II.—Annie E., aged thirty-nine, had been incapacitated for work by pain for five years. The trouble began suddenly with abdominal pain and the appearance of a tumor in the right lumbar region of the abdomen, which tumor was described as being hooked or J-shaped, about an inch in thickness. There were various remissions, and upon one exacerbation a quantity of pus was said to have been passed by the rectum. The pain, though varying, was continuous and never agonizing. When first seen, the tumor was cylindrical to the touch, extending from the right inguinal region to beneath the ribs, movable, and feeling like a tense cyst. There was considerable stagnation of gas and, feces in the larger bowel, but the stools were of natural color. A distended appendix or colon was diagnosed, and, from what she said, her attendant in a neighboring city had thought the same, and yet upon operation a distended gall-bladder was found.

A man, dying at sixty, had during the last ten years of his life paroxysms of pain over the region of the liver, but no other symptoms aided at finding a cause, and palpation was prevented by his fat. Still, for years he and his attendant took it for granted that gall-stones were the sole trouble, and operations were talked of. An attack of sickness brought to the patient thin abdominal walls, when was revealed an unexpected tumor. It was very movable, often below and to the left of the umbilicus, and from there moved to every part of the upper right quarter of the abdomen. In size, consistence, and form, as felt through the parietes, it was very like a kidney, and what a perfect picture of floating kidney the case presented! Occasional attacks of hæmaturia or suppression of urine following paroxysms

of unusual pain, so strongly suggesting twisting of the pedicle, the tumor movable, even to being elusive, in size and feel so deceptive—these led us to attempt to replace the lump in the loin, where it easily went, and when kept there by a binder seemed to give the patient some ease. Nephrorrhaphy was presented, but the patient in his exhausted state doubted his powers of endurance, and after many months of most awful suffering he succumbed. His last attendant was so kind as to let me make the autopsy, and he has in his possession the tumor—this gall-stone. It is pyriform, weighs two ounces and a half, is two inches and three quarters in length, and six inches and a quarter in its equatorial circumference. Two inches below it, in the duct, this smaller stone, the size of a large cherry, was found. Five facets make up the entire surface of the latter, one of which is polished and fits the facet in the point of the larger stone, and the two placed together make the pyriform shape of the gall-bladder. They were plainly at one time in contact if not in union. The sac, when found, was not much elongated, the stone resting just below the edge of the liver. The stone made a visible projection of the abdominal walls after death. These two cases, it is trusted, will show how deceptive exceptional cases of cholelithiasis may be.

In cases like these which have resisted all remedies, what is to be done? Plainly, operate. The ideal operation is this: Open the abdomen, incise the bladder, remove the stones, suture the opening in the bladder and drop it back, close the abdomen after it, leaving the patient eventually in the full possession of his organs. This, of course, can be done only when the cystic and common ducts are perfectly patent; otherwise the local back pressure of the bile would destroy the delicate scam in the fundus of the cyst. Circumstances have permitted this to be done very seldom. Very often the stone, or some of the stones, can not be found in spite of the most diligent search. Then to close the bladder, presuming it could be safely done, is simply to place the patient where he was before beginning the operation. So it has been advised to stitch the margins of the bladder to the margins of the parietes, thus establishing a biliary fistula for the escape of this calculus or of regurgitant bile, or for assisting the onward movement of the stone by the probe. The following case will illustrate:

CASE III. *Cholecystotomy.*—The patient, M., was a strong man of forty-one, who for two years had had occasional attacks of what was called dyspepsia, accompanied by tenderness in the right hypochondrium. These attacks increased in severity till six months before the operation; they assumed the character of biliary colic and occurred as often as every three or four weeks. Gall-stones were never found, but the distended gall-bladder was easily felt during the attacks and could not be at other times. His condition was serious from excessive jaundice, the persistent reflex vomiting, and the large amounts of morphine necessarily given to lessen pain. Attacks were now becoming so frequent that sometimes but four days intervened between them, and the offers of an operation were about to be accepted when a violent cystitis occurred, following a catheterization. The most terrible strangury, which nothing would lessen, made still more morphine necessary, and these, with the continued high temperature and loss of sleep, soon brought the patient to a state of extreme emaciation and asthenia. He now recognized the need of an operation to ward off a recurrence of biliary obstruction, which might come on at any moment,

and appreciated also the probable insufficiency of his powers to withstand either operation or attack. Under these critical circumstances it was decided to defer operating as long as possible to give time for recuperation; but, in case obstruction again occurred, to operate at once, as safer than to weather another attack. There were but a few days to wait until colic once more began, and accordingly, six hours later, with a temperature of  $101.4^{\circ}$ , the patient was placed on the table. The incision, five inches long, was made parallel with the cartilages of the ribs and three finger-breadths from them. The cyst was but slightly distended, presenting an inch and a half below the liver, which was somewhat enlarged. The former was raised by two loops passed through it, and incised between these for the length of an inch. Several ounces of clear mucus, tinged straw-yellow by the bile and in places mottled-brown, were evacuated, and with them a gall-stone the size of a marrowfat pea. Though this bore facets, no other stones could be found by the finger, either within or without the bladder, nor by a probe; but as one was known (from the jaundice) to be in the common duct at the time of beginning the operation, it was decided to establish a fistula to allow of its possible escape externally, and more because closing the sac securely would, in the face of the back pressure, hardly be possible. The opening in the latter was accordingly stitched by continuous suture to the peritonæum and transversalis fascia in the outer end of the parietal incision, a large tube inserted, and the rest of the incision closed. His temperature at once fell to  $99.4^{\circ}$ , and was not over that during his recovery. His colic, however, continued three days and ended, not by the extrusion of the stone, but by its entrance, as was to be supposed, into the bowel.

This is of interest as showing that such concretions are not advanced (through the duct) by fluid pressure alone, for the bile was flowing freely externally, but possibly by a peristalsis of the muscular coat of the duct. At the end of the third day the most violent vomiting began, induced, most likely, by the movement of the stone; it lasted all night, and before it was done consisted of gall, thus showing that the common duct was once more free. It did not stop until a very large evacuation from the bowels had been secured by a copious irrigation of castor oil and soap. Alarming hiccough then began, and was stopped in the same way after some hours. His emaciation now increased until two weeks later he was all but a skeleton; this was to be attributed to his cystitis, which was, fortunately, giving him less misery than before the operation. As the disease subsided, he was taken with severe pains in the lower limbs and joints in the nature of rheumatism, and after a week of these, then with the appearance of three mysterious, painful swellings in the axilla, on the scapula, and on the shin respectively. What these were, in the face of a normal temperature, no one could say. They slowly enlarged, one to the size of the fist, approached suppuration, and then declined. All these, it is unnecessary to state, added much to the discouragement of both patient and attendant, for the swelling in the axilla, together with his emaciated condition, and then a badly inflamed bursa over the third sacral spine, limited very much the position in which he could lie. Next came an attack of subacute bronchitis of a week's duration. Convalescence was, of course, much prolonged by this fateful list of miseries, but the fistula progressively diminished, and, in spite of the

copious discharge of bile, his weight reached, six weeks after the operation, twenty pounds more than it usually had been.

In case this stone, which was known to lie in the common duct, was found at the time of operating, what should have been done with it? First attempt to slide it back into the open bladder by pressure on the outside of the duct by the fingers; failing in this, to slide it onward into the duodenum, unless so large as later to hazard obstruction of the bowels from its size. The probe can also be tried for this purpose. If these are not successful, crushing the stone by padded forceps on the outside of the duct must be attempted, or the same thing by introducing needles into the friable substance of the stone. These failing, the duct must be incised and doubly sutured after removal of the obstruction; or, if this is impossible or contra-indicated, and the cystic duct and sac are still open, an anastomosis must be made between the latter and some part of the bowel for the diversion of the gall to its proper destination and the avoidance of a fistula. Sometimes, when the stone lies near the lower end of the duct, it can best be reached by an incision in the duodenum. The technic of the last four procedures will be neglected, as the intention is to write from personal experience as much as possible.

CASE IV. *Closure of Biliary Fistula.*—The above patient, M., was now up, and the fistula had contracted to the size of a needle-hole, but all the bile ran out of it in spite of many applications and expedients in minor surgery, and the stools remained perfectly white. It was feared the common duct had closed by some adhesive process following laceration by the last stone, or through disuse, as Langenbuch suggests, and to determine this the following test—an original one, it is believed—was made: A warm saline solution was passed into the fistula under a "head" of four or five feet. No current inward could be detected. The trial was repeated with olive oil with no better results. However, there grew to be occasional hindrances to the external secretion through granulations, and when these occurred the faces took on more color, thus proving to the patient's great good fortune that there was an inward channel and that steps could be taken to close the fistula permanently. Otherwise the outcome would have been, to quote Langenbuch's words, "a definite occlusion of the duct and a permanent fistula, two circumstances not promoting the comfort of the patient." But, in spite of the harm to clothing which the leakage occasioned, an operation was not considered until inflammation of the abdominal integument set in. Protectives and unguents had been carefully used, but still the inflammation grew until a large surface was quite raw and the patient could only lie on his back in bed with neither clothing nor covers on him. Thirteen weeks after the first laparotomy the second was undertaken. The old incision was opened an inch and a half just internal to the fistula, the internal surface of the fistula and cyst curetted, four stout silk ligatures drawn as tightly as possible around the elongated fundus of the bladder, and the whole opening firmly closed. The cyst walls were found so thick that sufficient constriction could not be brought to bear upon them by means of the silk; silver was not at hand, and the obstinate reappearance of the fluid was hourly expected. Surely enough, on the third day a drop of the clear mucus made its appearance, and two days later the bile. This so discouraged the patient that he bravely declared he would not leave his bed till he was well, and accordingly the hour was set for the third operation. Circumstances, however, caused him to change his mind, and he went

walking on the street six days after the last abdominal section! Only once again did *bile* appear, and the residual mucus of the gall-bladder gradually diminished till seven weeks after, when it disappeared, not, however, before two of the ligatures had been extruded. Whether these ulcerated *through* the walls of the bladder into the sinns or over its ends cemented in the parietes can not be said, but their appearance greatly mystified the patient, who was something of a mechanic. Since then, during a period of eight months, he has been in perfect health, weighing more than ever before and doing all his business.

CASE II (Aunie E., continued).—Cholecystotomy in two sittings.\* The patient would have nothing but an operation, so in July, 1890, a vertical incision three inches and a half in length was made just external to the right rectus and beginning an inch above the middle of Poupart's ligament. Later this cut was extended an inch upward. A distended gall-bladder was discovered, glistening and pyriform, and extending to the lower end of the incision. It was decided to stitch this to the parietes, after the general rule with pancreatic cysts waiting for adhesions, and at a second sitting to evacuate the organ. The walls of the cyst appeared as tense and thin as a toy balloon—a sufficient objection, it seems, to the suggestion made to this society by a member to produce always in gall-stone colic vigorous vomiting. This condition made stitching through its serous coat difficult, but an oval upon the lower end of the tumor, an inch and a half in length, was, by continuous suture of fine silk, attached to the parietal fascias at the lower angle of the wound and the remaining part of the incision closed. The open wound was packed. No rise of temperature followed above what had prevailed for a month previous—viz., 99.5°. The second operation was undertaken on the morning of the sixth day. Without anæsthesia the cyst was incised after passing a securing loop, and over a pint of clear serum resembling white of egg evacuated. It may here be desirable to explain that the natural secretion of the lining of the bladder is a clear mucus, and being here unmixed with bile, showed that communication with the common duct had been long cut off. Upon exploring, an ovoid stone an inch and a sixteenth in length was found resting against the under side of the anterior border of the (enlarged and locally inflamed) liver. Here a suppurative process had begun, probably toward extrusion as an end. The calculus was extracted after a little trouble by cutting in two by a penknife. Large drainage-tubes were used for a week. The mucous discharge progressively lessened for three weeks, when the fistula closed. This stone, of the "mulberry" variety, weighs one hundred and five grains and measures two inches and five eighths in its smallest circumference, is radial in structure, and floats in water. In the light of the second sitting it is plain that it would have been advantageous to have opened the cyst at once, the plan generally followed, we find, by other operators.

CASE V. *Cholecystotomy for Second Stone*.—Annie E. remained well for a few months, during which time the fistula occasionally opened and discharged a little clear mucus, and upon these occasions she felt somewhat better, as other patients similarly circumstanced have reported. But pain and tenderness returned, and at the end of five months she was again unable to do housework. Not only pain, but extreme tenderness, extended in the form of a girdle around her *left* loin, from near the middle line behind to the middle line in front, and the same existed over the site of the operation. It will be remembered that the gall-bladder was fastened within an inch of Poupart's ligament; and could tension from retraction cause this? Hardly the pain in the left side, but neither would residual gall-stones

seem to do so. An examination under ether failed to explain. When occasionally visited over a period of six months, she was plainly seen to be declining, and eventually took to her bed. Anxious to have anything done, she was offered a cholecystectomy with uncertain prospects, when a probing of the fistula revealed another stone, and her second operation was at once undertaken, thirteen months after the first. It was necessary to open the abdomen in the line of cicatrix, but only to a limited extent. Numerous adhesions were expected, but, in spite of the utmost care and deliberation, the liver was incised to the extent of an inch and a half by an inch. The hæmorrhage was alarming even from this small cut, and the Paquelin was in use elsewhere. But a packing of gauze dipped in a solution of chloride of zinc, twenty grains to the ounce, effectually removed this interruption. After opening the bladder enough to admit the finger the stone had disappeared, and it required considerable search, both within and without, to find it, and it is believed a sacculated dilatation of the duct (not a rare condition in these cases) concealed it both then and at the first operation. The stone was of the same variety as the first, somewhat smaller but weighing a little more. Cholecystectomy was now indicated to prevent any more intruders, but, from the dense adhesions, this was not attempted. In lieu of it, the following scheme was adopted, apparently without a precedent, and how wisely remains yet to be seen: In place of removing the viscus, why not ligate its duct, thus cutting it off from taking any part in the transference of bile? This was not easy, working almost against the vertebræ and including no other structures, but it was finished with two stout silk ligatures. A drainage-tube was placed within the lips of the cut in the liver and surrounded by a little gauze. The fragments of the fundus of the bladder were gathered together and stitched in the wound, a silver wire being placed between them and reaching to the outside to conduct out the mucus which it was expected would still be secreted from the mucous lining. The night of the operation showed a temperature of 103°, but this was but one degree more than three days before. This quickly fell, and seven days later tube and stitches were removed, and on the twelfth day she abandoned her bed. But her new-found ease was not to last. Pain and tenderness, very much as already described, again appeared, and again the question, from what cause? This time, however, the deep-lying and heavy ligatures might be suspected. After some months of discouragement electricity was applied, in the hope that the pain was neuralgic. The first application of the fine coil rapidly interrupted gave much relief, and three weeks of daily applications, made between the sacrum or flank and the incision, so helped the patient that with occasional applications she began again the whole work of a large house and has continued it till to-day—two months—with comparative vigor and little pain. She still wears the silver wire, and still feels indisposed and uneasy when its removal allows the fistula to close.

---

**Vivisection in Germany.**—"The Education Committee of the Prussian House of Representatives has lately had under consideration a petition from the 'International and Hanoverian Association for the Suppression of the Scientific Torture of Animals,' urging the absolute prohibition of vivisection. Both the House of Representatives and the Reichstag have already had the question before them, and the late Cultus-Minister, Dr. von Gossler, imposed certain restrictions on scientific investigators in respect of experiments on animals with the object of preventing any abuse. The majority of the committee were of opinion that science could not dispense with vivisection, and that abuses had only been proved to have occurred in a few isolated instances. Such exceptional cases did not, however, in the opinion of the committee, justify the total prohibition of vivisection. The House was therefore recommended to pass to the order of the day."—*British Medical Journal*.

\* Reported before in the *Cincinnati Lancet Clinic*.

- SOME CASES OF THE  
DERMATITIS HERPETIFORMIS OF DUHRING,  
WITH REMARKS ON THEIR ÆTIOLOGY.

BY GEORGE T. ELLIOT, M. D.,

ATTENDING DERMATOLOGIST TO THE DEMILT DISPENSARY AND  
THE NEW YORK INFANT ASYLUM;  
ASSISTANT PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

In a recent article on Dermatitis Herpetiformis\* I reported two cases, in each of which the origin of the disease could be traced directly to the reception of a severe mental and moral shock. Owing to this fact, and also because in their entire pathological course and history, they showed a profound subjection to influences of all sorts, which in one way or another expended their effects upon the nervous system, the conclusion was drawn that the *raison d'être* of the process on the skin was a disturbance of some kind brought about in the nervous system by the ætiological factors in existence, and from thence transmitted to the cutaneous surface. For these same reasons I also expressed my belief that the cases ought to be regarded as dermatoneuroses, and I stated that not they alone, but also all other examples of the disease, should, in my opinion, be included in the same category.

In support of this confession of faith, I would record the following cases:

CASE I (private practice).—Male, aged forty-five, was kindly referred to me for treatment on November 26, 1889, by Dr. Blundell, of Paterson, N. J. His disease had begun a year previously, and for many months prior to its inception he had been subjected to severe overwork, business worries and anxieties, and grave responsibilities. These circumstances had finally induced great nervousness, he suffered from severe neuralgic attacks, constant insomnia, and he became generally unstrung and neurasthenic. He could not say that any special determining factor immediately preceded the first appearance of the cutaneous disease beyond a qualitative and quantitative increase in his mental strain, but he had observed during its existence that new outbreaks had occurred whenever any fresh worry or anxiety arose or after any slight or severe nervous shock or disturbance. In fact, he even stated that regularly, a few hours or the next day after connection with his wife, a relapse of variable severity and extent would be manifested.

The eruption had first appeared in the lumbo-sacral region, but later quite generally over the entire body, though more especially over the extensor surfaces of the extremities. From the beginning he had never been free from the manifestations of the process, but relapses occurred continually, at times of limited extent, at others covering a wide territory. Pruritus had been a constant and severe symptom, not only on the site of the lesions, but also generally over the entire surface. Occasionally burning pain would also be experienced. During the existence of the disease the bowels had been regular and the appetite good. Once in a while he suffered from slight indigestion. A "brick-dust" deposit in the urine had been frequently observed.

*Status Præsens.*—The patient was slight, wiry, and of medium height. His functional health was good. The urine contained urates, uric acid, and oxalate of calcium to a marked degree. The eruption occupied the lumbo-sacral region, the extensor surfaces of the arms, especially about the elbows, and extended over the shoulders. The buttocks and external aspects of the thighs and legs were affected, but the lesions were aggregated together,

more abundantly about the knees. It was noticeable that almost perfect symmetry was followed in the distribution of the lesions and patches. On the surfaces mentioned papules, papulo-vesicles, and vesicles were met with. These were occasionally discrete, but for the most part arranged in groups of variable extent upon a reddened, somewhat elevated base, and they varied in size from that of a pin-head to that of a small pea. The vesicles were tense, deep-seated, rounded, stellate, or flattened, and contained a clear, slightly yellow fluid of neutral reaction. The papules resembled somewhat those of urticaria, as also did larger erythematous patches, which were distributed here and there, but, in contradistinction to the lesions occurring in that disease, they were persistent in character, only disappearing gradually and then leaving pigmentation. Abundantly distributed over the surface were dark pigmented spots and areas, the residua of previous lesions, and there were also crusts and scratch marks. The itching was bitterly complained of and was said to be most severe at night, at times paroxysmal in character and accompanied by a sensation of heat and pain.

While the patient was under my care, the course of the disease at first was one of alternate improvement and relapse. The relapses and recurrent outbreaks followed regularly after any worry, anxiety, or increased mental work. Several times, the day following a coitus, I was able to observe on him more or less abundant new lesions and patches, and he complained of increased pruritus. The character of the eruption varied in the relapses, at times papular and vesicular, or purely vesicular, or the latter and bulbous, or again a mixture of all three forms of lesions with, in addition, erythematous patches of variable extent.

At the end of a few months, there being still no cessation of the mental worry, the overwork, etc., the treatment also being ineffectual, the patient was ordered to take an entire rest and to go away for some weeks. He remained in the country for six weeks, and on his return reported that the outcropping of lesions had ceased at the end of the first week; the pruritus had diminished greatly. The insomnia also had been relieved, he gained flesh and strength, and on his return felt better than in several years. He could now attend better to his business, but still got tired easily. A week, however, after taking up his old cares and responsibilities and worries, pruritus began about the ankles, and groups of papules appeared around the knees and on the legs. He was ordered to take a long rest and went away from business and work of all kind. He regained his general health completely, the eruption disappeared, and since May, 1890, he has remained well.

CASE II (private practice).—J. H., male, aged forty-two, an electrical machinist, consulted me October 5, 1890. He stated that he had always been of a nervous temperament, excitable, prone to worry and to restlessness. The nature of his work had also necessitated constant watchfulness and anxiety, owing to its dangerous character. In 1876 a falling window shutter struck him on the right shoulder, fracturing the clavicle and four ribs, and for more than a year after he was unable to use the right arm or leg. In 1883 he had a severe attack of dysentery and, when barely recovered, he failed in business. In 1884 he lost his four children inside of a few weeks. His wife's illness began in the following year and has persisted ever since, but it was severer for him during the first year, as, owing to his poor circumstances, he was obliged to work during the day-time and take care of her during the night. He thus had little rest and sleep, and this, conjoined to his mental suffering, the severe moral shocks he had experienced, and the harassing anxiety of poverty and debt, operated an entire change in his character, causing him to become gloomy, despondent, and melancholic. In 1887 he broke his left leg, and his circumstances became still

\* *Journal of Cutan. and Genito-urin. Dis.*, September, 1891.

more precarious, but, finally recovering, he began work again. During May and June, 1889, he worked in a damp cellar containing pools of stagnant water. Early in May attacks of quotidian malarial fever began, and at the end of two or three weeks he felt a most intense pruritus over the buttocks. When he examined himself, he found that they were covered with an eruption of "small water blisters and bumps" (vesicles and papules?). A week later the face became swollen, very itchy, and a similar outbreak ensued upon it, and extension of the process to the trunk and extremities gradually took place.

Since that time the patient has never been free from the disease, but crop after crop of lesions have appeared, vesicles, papules, bullæ, and large "hives" occurring simultaneously, or the one form or the other predominating in successive outbreaks. The pruritus has always been most intense, interfering with his rest, causing loss of appetite and flesh, and even at times forcing him to abandon work for days in succession. During the course of the disease the patient constantly observed that severe itching invariably preceded an outbreak of lesions on any part of the surface, lasting for an hour or more, but abating somewhat with the appearance of the objective manifestations. Symmetrical distribution of the lesions was also noted, and when an outbreak occurred on one side of the body it was invariably followed within twenty-four hours by a similar crop on the opposite side. An increase in the degree of the itching and in the amount and intensity of the eruption followed regularly after the reception of any shock, or with any accession of worry, or when his work demanded more watchfulness than usual—in other words, whenever, from any cause whatever, an additional mental strain or effort was required of him. Continuous pressure upon any portion of the body was also followed upon that part by an outbreak of lesions. Clonic spasms and jerkings of the legs, but especially of the arms, were also complained of as occurring when in bed, and lately, after a severe wetting, a numbness of the extremities had developed and lasted for several weeks. Shooting neuralgic pains had also begun at that time and still occurred, being invariably followed by a crop of lesions.

When seen by me the patient still suffered from occasional attacks of quotidian malarial fever, but they did not appear to be followed by any outbreaks of the cutaneous manifestations. He was thin, much run down, anæmic, and very constipated. Anorexia, but no gastric derangement. Urine abundant and normal.

The entire surface was occupied by the eruption, except over the abdomen and flanks. Very marked symmetrical arrangement was observed. The morbid phenomena consisted of vesicles, papules, and pustules grouped in patches and also occurring discretely, covering more or less large areas, lying contiguous to each other or separated by intervening masses of crusts or by pigmented spots and surfaces of variable extent. Every stage and grade of the process was apparent on the skin from the fresh vesicle or papule or other lesion to the crusted one, or the pigmented spot, or in many places to the superficial cicatrix, the result of the wounding and tearing of the skin by the nails in the patient's endeavor to obtain relief from the itching. The body presented in consequence a most peculiar appearance, which, however, bore testimony to the severity of the disease and the suffering entailed by it. While the patient was under treatment there was no cessation in the outbreaks of the process, but crop after crop appeared, consisting of lesions of all forms. Occasionally large erythematous patches developed, upon portions of which numerous vesicles would be aggregated, or tense bullæ would arise suddenly upon an intensely itchy or burning surface, or groups of papules would appear and remain as such, or become transformed into papulo-vesicles. The most

protean course was shown by this case; but yet the tormenting and implacable itching persisted unchanged and uninfluenced by the condition of the patient, by the paucity or multiplicity of the new lesions, or by any treatment made use of. After being under observation for some months, the patient disappeared from view, being still in *statu quo ante*.

CASE III (dispensary practice).—L., male, aged forty-five, consulted me in September, 1890, giving the following history: Two years before the eruption began he experienced severe family troubles, and these still continue. At the same time he suffered business reverses, and he has never recovered his former position in life. As a result, he became greatly depressed, the periods of depression alternating with others of severe nervous excitement and restlessness; he suffered from insomnia and sudden and unaccountable feelings of oppression and night terrors. The patient had had several years ago malarial fever, and also an attack of pneumonia. His functional health had been good; but the new occupation he followed caused him considerable excitement and necessitated exposure to cold during the winter months.

The eruption first manifested itself two years before I saw him, beginning as an outbreak of pustules on the inner side of the right upper arm. The same manifestations soon appeared on the left arm and gradually implicated the trunk, and later on the lower extremities. From the first appearance of the lesions he has never been free, though their type shortly changed to the existing one. The pruritus and burning sensation, which had been always a prominent symptom, has increased greatly in degree. When the patient was examined he was found quite well nourished, bowels regular, stomach in good order, urine normal. His habits were good; he drank beer with his dinner, but did not over-indulge in stimulants. The eruption was distributed quite generally over the face, arms, and legs and trunk, consisting of erythematous, slightly elevated, sharply defined patches of all shapes and sizes. They were round or oval or irregular in outline, and from a silver dollar to a whole hand in size. Their color was for the most part of a purplish-red; some had become purpuric. Besides these, there were groups of papules, here and there small crusted areas, and more or less large pigmented surfaces, the sites of former lesions. The pruritus was intense. While the patient was under observation it was seen that the erythematous patches began as small lesions, the size of a thumb-nail perhaps, and then gradually enlarged to a silver dollar or much larger size, no involution of the central portion taking place. The patches were not transitory in existence, but remained persistent for weeks and months, only slowly disappearing and then leaving pigmentation. There were no outbreaks of vesicles or pustules or bullæ while under my care; only a few groups of papules. In December the patient was much improved by his treatment, and was not seen again until March, 1891, when he presented himself with a new but slight relapse. It subsided shortly, but he returned in June with another and similar erythematous outbreak. In September he again presented himself with a new relapse, affecting especially the face. The lesions were symmetrical on both temples, forehead, and cheeks, consisting of thickened, elevated patches on which were papules, vesicles, and crusts. The pruritus was very severe. This relapse has persisted without material change up to the present day (February, 1892), having become general over the body.

From the clinical histories of these three cases it can be seen that each possessed, in common with the others, certain prominent and striking characteristics, which would immediately suggest their intimate relationship, and tend to establish the fact that each constituted an integral part

of one and the same process. It can not be said that there was an absolute quantitative and qualitative identity in their objective and other symptoms, but yet all were characterized by chronicity and long duration, by frequent relapses, multiformity of lesions, excessive subjective disturbances—pruritus and burning pain—and by rebelliousness to treatment. Possessing, therefore, these essential features, it would be impossible to regard these cases as any other form of disease than dermatitis herpetiformis, if we accept the writings of Dr. Duhring and are familiar with the superb analysis of the subject made by Brocq. If, however, we base our diagnosis upon the objective lesions alone and do not take the entire course of the disease into consideration, then certainly difficulties will be met with at every step, for at one time the eruption could be regarded as an eczema, at another a herpes, or an urticaria, or some other process. It scarcely seems necessary to me, however, to point out the differential characteristics of Cases I and II, when their entire clinical histories and course are duly valued, and the same may be said, in my opinion, in regard to Case III. Yet, for the reason that, when I presented the patient before the New York Dermatological Society, some of the members present were inclined to regard the eruption in this case as a chronic urticaria, I would point out those points which appeared to distinguish it from that of dermatosis. There was not observed during the entire time that the patient had been under observation any sudden and daily outcropping of wheals, which, after short duration, would disappear, but the lesion began as a small erythematous patch, which gradually enlarged to the size of a silver dollar or much larger, and then persisted for weeks and weeks, finally and gradually fading and leaving pigmentation. The lesions in no instance resembled those seen in urticaria, but were sharply defined, slightly elevated, and of a dusky-red color. In addition, there was not any of the irritability of the skin seen in urticaria; no wheals or lesions could be evoked by rubbing, scratching, or by other means. Finally, sections of the newer lesions under the microscope showed distinct inflammatory changes, such as do not exist in urticaria.

CASE IV (New York Skin and Cancer Hospital, Dr. Bulkley's service).—A man, aged thirty-eight, entered the hospital on November 16, 1889. His general health had always been good. He had never had syphilis or any other disease; had always been temperate, though accustomed to drink a few glasses of beer at night, but no whisky. For months before the cutaneous process began he had been subjected to excessive mental worry, anxiety, and fatigue, superinduced by certain duties in connection with one of the more or less large secret societies of the country, and the nervous strain had led to insomnia and a general lowering of his physical and mental powers. While in this condition he observed, toward the end of July, 1889, immediately after experiencing a keen disappointment, the appearance of an elevated, reddened, somewhat scaly patch, as large as the palm of the hand, over the middle portion of the sternum. It was accompanied by severe itching and burning pain, and persisted until the middle of September, when an outbreak of similar lesions occurred over the shoulders and back, at the flexures of the elbows and at the wrists, over the knees, and on the palms and soles. The latter burned and tingled, while the rest of the surface itched intensely. He stated positively that the

lesions were dry, pointing out some similar to them; in other words, papules, except on the soles, where they consisted of bullæ the size of a small pea. All treatment seemed to be without effect, and the nervous strain he was under continuing and increasing in degree, in a few weeks (October) bullæ, pea-size to that of a hen's egg, formed about the ankles, and the legs became œdematous from the knees down. At the end of a couple of days subsidence of the œdema occurred, and bullæ began cropping out all over the legs. At the end of a week the thighs had become similarly affected, and a little later the buttocks and forearms. Over the remainder of the body only few bullæ formed, papules largely predominating. The outbreak of these lesions had invariably been preceded by the most intense pruritus, which would cease when the bullæ had been ruptured. The mucous membranes had at no time been affected. The onset of the bullous eruption had been accompanied by more or less elevation of temperature and constitutional disturbance.

*Status Præsens.*—Patient medium height, slight build, of energetic nervous temperament. Appetite and digestion good, bowels regular. He can walk only with great difficulty, *not*, however, from any loss of power, but on account of the inflammation about his ankles and the pain therefrom. On the flexor surface of the left wrist and on the upper portion of the right arm, as well as on the penis and scrotum, are large patches of vitiligo, which have developed since the inception of the cutaneous disease.

The entire surface of the body, except the forearms and legs from the knees down, is deeply pigmented, and quite thickly distributed over it are small crusts and groups of firm papules. On the legs and forearms are bullæ, in size from that of a large pea to that of a pigeon's egg; some tense; others flaccid, grouped, and discrete. Some large ones had been evidently formed by the confluence together of smaller lesions, which, in some instances, were seen grouped around and about the bullous elevation. Their contents were clear yellow, or had become turbid or even purulent. Where the fluid had dried, thin, yellowish, and blackish crusts were seen, but occasionally, instead of these, a ragged, irregular loss of tissue had been produced by the patient's scratching. About the ankles the crusting was very marked, the skin beneath deeply fissured, denuded, and bathed in a sero-purulent fluid, having a most offensive odor of decomposing pus. Acute inflammatory reaction had been set up, and the pain, as already mentioned, prevented him from walking. That no other cause produced the apparent inability to walk was later distinctly demonstrated by the fact that, when those morbid symptoms had been removed by proper antiseptic treatment, the patient was able to get up and go about with ease.

The record of temperature was not begun until November 18th. It was then 101.2°, and up to December 1st it varied between 99° and 102.2°, evening exacerbations and morning remissions. The pulse was rapid and small—98 to 144. These conditions of pulse and temperature can not, in my opinion, be ascribed to the disease dermatitis herpetiformis, but rather to septicæmic infection from absorption of the products of decomposing pus. The source of infection having been completely removed by November 28th, it was seen that the temperature fell to normal, and remained there during his stay in the hospital, except for a few days, when the temperature again rose to 100°, in consequence of a neglect of antiseptic precautions.

While the patient was under observation, numerous outbreaks occurred, and crops of bullæ, or papules, or papules and vesicles, or of all combined, appeared in more or less rapid succession. Bullæ, however, developed only on the legs, below the knees, or occasionally on the backs of the hands or on the wrists. Usually single and discrete, at times they were small

and grouped, or again around a central large one would be arranged a row of smaller bullæ.

The vesicles varied in size from that of a pin-head to that of a small pea, tense, rounded, or flat, or angular or stellate. They formed small groups and also large patches, the latter being composed of papules and vesicles arranged and aggregated together without regularity. The papules were firm and erythematous, occurring as above mentioned, and also in more or less large groups and patches.

These various lesions, when left to themselves, underwent involution in a few days, the vesicles and bullæ forming crusts, and the papules leaving marked pigmentation. A group of vesicles appeared at one time on the left cheek, near the nose, which, however, did not subside *in situ*, but progressed over the surface, and in a few days had the appearance of a reddened and infiltrated patch, bounded by a scalloped elevated border, upon which was a row of small vesicles and crusts.

The outbreaks of the eruption, of whatever character or extent, were always preceded by the most intense itching, and the pruritus persisted until the bullæ or vesicles had been ruptured, or the tops torn off from the papules. The patient remained in the hospital for some months, leaving February 8, 1890. He was then in good functional health, and had gained flesh and strength. The cutaneous surface, with the exception of deep pigmentation, was free from disease. Here and there were a few crusts and excoriated places, but no new lesions or crops had appeared in some time, and the itching had ceased entirely. He remained under observation for some months, and occasional bullæ dropped out on the legs, and small groups of papules and vesicles on the arms. These outbreaks finally subsided and no new relapse had occurred up to the end of 1890.

Whether he will or will not experience a return of the disease it is almost impossible to say. Possibly not, as he is no longer subjected to those influences which appear to have been active in the production of the primary attack of the process. Before this patient entered the Skin and Cancer Hospital he had been seen by Dr. Piffard. He has made a brief reference to the fact in an article on Pemphigus Pruriginosus, accompanied by two photographs of the case, which he published some time later. In this paper he says that while he does not believe that this and similar cases are in any way related to pemphigus vulgaris, while he denies their relationship to either of the affections termed herpes, though granting that Dr. Duhring would include the case in question in his dermatitis herpetiformis, he yet prefers to use the term pemphigus pruriginosus for want of a better one and until some correct title and more definite knowledge of the etiology and nature of such processes is obtained. I would agree with Dr. Piffard that the affection has no relationship with pemphigus vulgaris, and though this case would undoubtedly have been termed pemphigus pruriginosus by the older writers, in view of the presence of bulke and pruritus, yet that alone is not a reason why we should persist in the use of a designation misleading and unsatisfactory. Because it has been handed down to us from former times, is no guarantee of its correctness any more than bullæ, accompanied or not by itching, always constitute a pemphigus, qualified or not by the term pruriginosus, and no other cutaneous disease. In the case in question here (Case IV), as well as in other similar ones, moreover, the diagnosis should not be based upon the objective lesions seen at only one and a single consulta-

tion, but the whole course of the process—the various pictures presented by it, the morbid phenomena of all kinds which arose—should all be taken into consideration and properly estimated in reference to each other before the case is definitely catalogued. This patient, who was under my immediate observation for months, presented, as predominant lesions, frank inflammatory papules, persisting for days, some becoming papulo-vesicles, and finally disappearing, leaving marked pigmentation. Pure vesicles were at times present, but only exceptionally bullæ, and these latter limited to the surfaces below the knees and to the wrists. In other words, we found that the *sine qua non* of a pemphigus—bullæ—were greatly in the minority and limited in distribution, and under those circumstances it would seem only to cause confusion more confounded to regard it as in any way connected with pemphigus vulgaris. When, on the other hand, the case conformed in its course and clinical history so closely with the others recorded here, then its inclusion in the category, dermatitis herpetiformis, would appear to be perfectly justifiable in my opinion—one supported likewise by Dr. Bulkley, in whose service the patient was.

The clinical features presented by these four cases do not appear to me, however, to possess as much importance as do the etiology and the pathological course of each, owing to the fact that from the former many facts could be gleaned which, taken in conjunction with the latter, pointed very suggestively, and in truth strongly, to an intimate connection of the cutaneous disease with some disturbed state or condition of the nervous system. We thus find that each of the patients had been subjected for a more or less long period of time before any outbreak had occurred on the skin, to varying degrees of physical, but more especially of mental, overwork, or grave cares and responsibilities, severe worries and anxieties, and grief. The influence of these\* factors upon the individual was demonstrated by the production of such evidences of general nervous and cerebral exhaustion as neurasthenia, insomnia, night terrors, depression alternating with periods of excitement, attacks of melancholia, severe neuralgias, etc., and it was during the existence and continuance of the state of nerve exhaustion that the process developed on the skin, although there was no evidence that these conditions acted directly and causatively in the production of the disease. On the contrary, and as will be shown presently, entirely different factors immediately preceding the appearance of the dermatosis, and apparently ushering it in, they could be accused as the direct causes of its development.

Besides the four cases (I to IV) contained in this paper, there are four others which I would also include in my analysis, for the reason that in them the various influences, agencies, causes, etc., which made up their etiological history and which participated in the origin of the disease could be obtained from the patients. Of these four, two (V and VI in my analysis) have already been reported by me, while the remaining two (VII and VIII) are as yet unrecorded.

The investigation of the histories of these four patients (V, VI, VII, VIII) showed the following factors to have

been in existence prior to the development of the disease :

CASES V AND VI.—Both neuropathic from worry, anxiety, mental and physical excesses of longer or shorter duration, run down in health, and debilitated.

CASE VII.—A woman, aged forty-eight, a sufferer from intense neuralgias for twenty years, nervous, hysterical, and easily frightened, subject to attacks of melancholia.

CASE VIII.—A woman, aged fifty-three, of nervous temperament and nature, having a lacerated cervix and excessive leucorrhœa of twenty-five years' duration, anæmic and debilitated, accustomed to take cold baths every day during menstruation, but not at other times.

If we analyze the ætiological facts presented by these eight cases as having preceded the development of the cutaneous disease, we find that they may be summed up and separated into the following two categories :

I. Excessive mental and physical work, mental and moral emotions, anxieties, cares, responsibilities, grief, etc. (Cases I to VI inclusive)—six cases.

II. Nervous temperament and nature, hysteria, intense neuralgias, anæmia and debilitating conditions, etc. (Cases VII and VIII)—two cases.

From the histories of the patients we furthermore found, as already mentioned, that the effects of the factors contained in the first category were shown in I to IV by the production of neuropathic states of the general system—neurasthenia, insomnia, etc.—while in V and VI there was in addition a debilitated, run-down condition of the general economy. In VII and VIII the consequence of the facts mentioned in II were systemic debility, great increase in nervous and hysterical condition, in frequency of neuralgias and other evidences of disturbed innervation, a more or less apathetic state of the mind, the conditions existing pointing in general to lowered nerve tone, without any special feature being demonstrable. The morbid symptoms and states having been produced in these patients, they persisted for various periods of time—from a few weeks to years; but, nevertheless, every one of the cases, during their existence and continuance, however long it might have been, enjoyed complete freedom from any cutaneous process. Upon the supervention of an additional or new factor, however, which apparently swept away the last remaining barrier to its production, then the catastrophe was precipitated, the dermatitis herpetiformis developed, and the usual train of symptoms characterizing the process became immediately manifested. These we find to have been in three cases severe mental and moral shock and emotion; in two (V and VI) from a death; in one (IV) from a keen disappointment; in one (I) a great increase in mental and moral strain; in another (II) malarial intermittent fever; in two (VII, VIII) the menopause. In the two last the process developed almost synchronously with the cessation of menstruation, in the one (VII) having been preceded for a month by the most intense pruritus, and the cutaneous disease has lasted now in Case VIII two years and a half; in Case VII, two years. Case III was unable to furnish any positive or definite data in regard to the inception of the process, though possibly some occurrence in

his profession—he was a sheriff's officer—may have ushered it in.

If we make a brief *résumé* of the histories of these patients prior to the development of the dermatosis, we find, therefore, on the one hand, a whole series of factors acting detrimentally upon the general system, but not provoking the disease, and on the other, in seven of them the occurrence of some new and different one immediately followed by the process. The question which therefore arises is, What rôle does each of these play in the origin and production of the dermatitis herpetiformis?

In disease in general, whenever it has been possible, a most material difference has always been made between those influences, conditions, etc., which, not productive of a process, act only as favoring or contributive factors, and those others which, immediately followed by the disease, can be regarded as the exciting and determining causes; and, in my opinion, the same course should be followed in dermatitis herpetiformis. Therefore, since all the factors contained in Case I, notwithstanding their existence and continuance for more or less long periods of time, were productive of a neuropathic condition, an increased nervous susceptibility, a generally lowered systemic stability alone, but in no instance, as we have seen, of the cutaneous disease, then they would have to be regarded as occupying the position of favoring or contributive causes—those which produced in the patient that state to which the term predisposition may be applied. On the other hand, however, since the cutaneous disease developed immediately upon and after the supervention of some new and additional occurrence independent of those which had been for a more or less long time in existence, and represented in my cases by the mental and moral shock, the malarial fever, the menopause, etc., then these should, under the circumstances, be considered as the active and exciting causes of the process—the ones which were directly and actively productive of its development.

From the ætiological data furnished by these eight cases, it seems to me that we can properly make the above division, and we thus have on the one hand certain factors which predisposed the individual to the development of the skin affection, and on the other hand certain others which directly caused its appearance, presumably, however, in virtue of this state or predisposition already in existence. Of the two, it is the "predisposition" which would seem to be the most important portion of the subject. What is the predisposition, what are the conditions which constitute it, and what actual changes take place in the general system in its production? are questions of pre-eminent interest, but, unfortunately, to-day not any more facile of explanation in dermatitis herpetiformis than in many other diseases, local as well as general. With our present knowledge and as yet limited opportunities for ultimate investigations, it is utterly impossible to precise the actual pathological changes produced in the patient by the ætiological moments which held sway prior to the development of the process, and we can only judge from clinical data what portion of the general system has been affected by the influences at work and where the disturbances, whatever they

may be, are probably located. It is upon clinical grounds alone, therefore, that I have based the opinion I hold that whatever the actual changes are which arise and are produced in the general system and thus constitute the predisposition to the dermatosis, they are resident in and intimately connected with the nervous system. I would locate them there for the reasons that in all those of my cases from whom an intelligent history could be obtained, the aetiological factors which preceded the disease were such as exerted their influence only upon the nervous system, or the patients were by nature neuropathic, or owing to some pathological systemic condition presented more or less well marked indications of disturbed nerve tone. When, in addition, there were not any other moments which could be accused as participating in the production of the state of the individual, and the results of the aetiological data mentioned were seen and shown by the various neuropathic conditions which developed in each—the neurasthenia, etc.—then it appears to me that, though there is no actual demonstration of nerve changes, yet the clinical histories of the cases furnish sufficient grounds for the belief that the predisposition was constituted by some condition other than normal of the general nervous system.

Regarding the predisposed condition of the patient as the most important, then the character of the exciting or determining cause would not be of such incisive moment, nor would it need to be a constant one. On the contrary, it seems to me that under those circumstances almost any occurrence, agent, or factor would be sufficient to precipitate the production of the process, and this is precisely what was seen in my cases, in seven of which the exciting cause was of the most various nature, character, and intensity. I do not think it worth while here to speculate upon the manner in which these exciting causes acted in bringing about the dermatosis; we know nothing whatever in regard to this portion of the subject, and possibly we never will, for though, in some cases, evidences of peripheral nerve degeneration may be found, in others, graver central changes, yet when the clinical history and course of the great mass of the cases are considered, it can not but be surmised that the changes presiding at the birth and existing during the continuance of the disease must be for the most part transitory, probably functional, and certainly not organic.

The analysis of the eight cases of dermatitis herpetiformis contained in this paper and the data furnished by their clinical histories allow me, however, I believe, to formulate the following conclusions:

1. That in the production of the dermatosis there are two factors in operation—a predisposition of itself not productive of the process, and an exciting cause capable of provoking the disease on account of the existence of the former.

2. The predisposition, present by nature or acquired through the influence of various causes, is constituted by a state or condition other than normal of the nervous system.

3. The exciting factor need not be a constant one, but

may be of the most various character, nature, or intensity, its power to call the disease into existence being, however, dependent upon the state of predisposition of the patient. As a result of these conclusions, I would therefore regard dermatitis herpetiformis *not* as a specific disease, always the product of a single or specific agent or cause, but as the outcome of any number of causes of the most various character acting upon an individual possessing a certain degree of predisposition.

It appears to me that if we take the dermatosis upon this broad pathological basis, we can understand the contradictions in origin met with in successive cases and their apparent entire want of agreement. It can not be expected that the predisposition would always be of the same degree, but it probably varies within wide limits, so that in one case an intense exciting cause, while in another only a slight one, would be necessary to produce the disease. We see, for example, among my own cases that V and VI, in whom the influences producing the predisposition were of comparatively short duration and it was slight, a severe and intense shock developed the process, while in Case I, the predisposed condition being of long existence and marked, a mere increase in mental and moral strain was sufficient. In Case II, again, we see a man undergoing and resisting for years mental and moral shocks, grief, etc., sufferings of various kinds, and finally succumbing to an attack of malarial fever. It is in view of such facts that the opinions expressed by me have been formed, and they are advanced for the reason that they appear to me to suggest a satisfactory explanation for the various and divergent modes of origin seen in the disease and the want of agreement manifested in the development of the individual cases. I must confess that my views do not apparently seem to be borne out either by all of my own cases or by those recorded in the literature of the disease. Still I do not believe that this is due to the absence of predisposing and exciting causes in the genesis of the other examples of the process, but rather, to judge from my own experience, to the ignorance and forgetfulness or intentional concealment of facts on the part of the patient. This is met with in a large number of cases, while in others the aetiological factors may have been of such slight grade as not to have excited special attention, and certainly in some it may have been due to the observer, who failed to investigate carefully the antecedent history of a case coming under his care. I do not, however, intend to analyze from this point the literature of dermatitis herpetiformis, having preferred to base my opinion upon my own cases alone, of which ten—eight in this paper and two others unrecorded—out of sixteen furnished facts such as have already been related, and I would rather take up the question of the nature of the process, whether it is a dermatoneurosis or not. In view of the data derived from the study of the aetiology of the cases conjoined with the clinical and pathological course of each, I do not see what other conclusion could be made by me but that the process is a dermatoneurosis. While the patients were under my care and observation, it was constantly shown that the cutaneous phenomena were peculiarly and altogether subservient to every influence which acted in any way upon the nervous system,

or which produced a nerve disturbance of some kind or other, and that it was independent of those which acted upon other portions of the general economy. Every mental or moral shock or emotion of whatever grade, worry or anxiety, excitement or fatigue, mental activity and work, etc., were regularly followed by an increase in the objective and subjective symptoms or were productive of a fresh relapse. Some of them, especially Cases I, V, and VI, would be entirely free from any and all traces of the process, but would have an outbreak immediately after the occurrence of some one or other of the factors just mentioned, and yet during the intermission there had been functional disturbances, gastric or intestinal or of other nature, but nevertheless no reappearance of the eruption. Other factors, which can be mentioned, and which acted in the same manner as those above, were coitus, the excitement and fatigue of the theatre or of any social gathering, the occurrence of neuralgias, shooting pains, hemicrania, etc. In regard to these latter, it was also observed that, together with a great increase in the subjective symptoms, there would be an outcropping of lesions over the surface which had been the seat of the neuralgia, pain, etc., and not over some other portion of the body. As it has been my experience to make these observations continually and repeatedly, to see on the one hand that the cases offered in their aetiology facts and data all pointing to the nervous system, and on the other that the process once instituted was entirely under the control of that system, it therefore seems to me that any other conclusion but that the process is a neurosis, or, since all its phenomena occur in connection with the skin, that it is a dermato-neurosis, is impossible.

In conclusion, I would add a few words in regard to the treatment of the disease. My experience has certainly demonstrated to me that there is no remedy, drugs, or forms of treatment which exercise any specific influence over the process. On the contrary, the few good results obtained by me have been only in those cases in which there was an opportunity of either removing or of counteracting the aetiological influences which had been at work, and it appears to me that the course of treatment adopted should be based upon that principle. I have not seen any particular benefit derived from dietary changes, from internal remedies, or from the routine administration of alkaline treatment, or nerve sedatives, or tonics, etc., as long as the primary influences operating upon the patient continued. But when, as in Case I, the individual was able to go away and be free from all his cares and responsibilities, etc., or, in Case IV, all his mental and physical overwork, etc., were replaced by rest and freedom, or, in Case V, the patient was protected in her business and family life from emotions, shocks, etc., or, in Case VI, recuperation of the general normal tone was obtained and retained by constant care, then the patients got apparently well—that is, enjoyed entire freedom from the disease, though this freedom lasted only as long as the primary causes were absent; but, as was seen in all of them, the eruption returned in some degree when they again came into play. On the other hand, no improvement was seen when the aetiological causes were

still in existence, notwithstanding the use of arsenic, atropine, ergot, strychnine, valerianate or phosphide of zinc, potassium salts, mercury, etc., and the hygienic and dietetic and other means employed. This was seen in Case II, whose mental sufferings continued; in Case III, who, from his occupation and family troubles, was incessantly exposed to shocks, mental and moral, to excitement, etc.; in Cases VII and VIII, whose nervous conditions and states and systemic disabilities remained in existence. In these four cases the patients' circumstances, surroundings, etc., precluded the removal of the detrimental influences primarily operating in the production of the disease, and, in consequence, it is still in existence, varying in degree from time to time, but yet never absent. From this experience, the course of treatment which should therefore be followed ought, in my opinion, to be based upon the broadest principles and, as far as possible, guided and directed toward removing all of those influences which apparently produced the disease in any given case, and which brought about the occurrence of relapses. If this can be done by appropriate internal treatment, then the remedies indicated should be exhibited, or, if it requires change of scene, surroundings, occupations, etc., then recourse should, as far as possible, be had to these. At the same time, any functional or other systemic disturbance should be attended to, and the patient's condition be brought as far as possible up to the normal. In other words, the therapy of every case will have to be based upon the indications and conditions existing in each, and can therefore in no particular be a specific one or consist of any specifics.

The external or local treatment is also of great importance, and should be combined with the one just mentioned. Its principal object, in my estimation, is to give relief to the subjective discomfort, to remove the lesions already existing, and to prevent septic infection, which, on a surface presenting so many points of entrance as the scratched and torn and denuded skin of a case of dermatitis herpetiformis would occur most easily (*vide* Case IV). I have tried to attain these ends with the tars, carbolic and salicylic acids, camphor, resorcin, menthol, chloral, ol. hyoseyami cocti, etc.; the sulphur treatment recommended by Dr. Duhring has also been used by me; but none gave results in any way commensurate with that obtained from ichthyol, and the majority failed altogether to be of any use. The ichthyol in ointment form did not act as well as when used as a lotion—twenty-five grains to fifty grains in an ounce of water; but the best effects were observed when it was combined with ol. amygdal. dulc. and lime-water:  $\mathcal{R}$  Ichthyol. ammon., gr. xxx to xl; ol. amygdal. dule., aq. calcis,  $\text{ãã}$  3 ss. This was rubbed in thoroughly several times daily and allowed to remain on the surface, or sheet lint saturated in it was wrapped around and retained in place by bandages. The treatment was also combined with frequent baths of starch, or of starch and bicarbonate of sodium, to which, in case there was much hyperidrosis, as was at times observed, a decoction of white-oak bark was added. By these means the patient obtained at least considerable comfort, even though they did not act as distinctly curative agents.

## HINTS ON COUGHS: THEIR CAUSES AND TREATMENT.

BY WALTER F. CHAPPELL, M. D., M. R. C. S.

No symptom of a disease befalls the young practitioner more than the varieties of coughs which he is called upon to treat. No symptom receives more random guesses or more shot-gun prescriptions. It is not my intention to wade through the ancient history and literature of coughs, but simply to give some practical hints on the varieties, causes, and treatment of coughs as they occur in every-day practice.

A cough, as we all know, is a symptom of some irritation, mechanical or sympathetic, affecting the respiratory tract or organs. It is Nature's effort to remove the cause of irritation.

When thinking over the best way to present this subject, I found it difficult to make a classification which would separate and at the same time include the important forms of cough. A division based on their relative frequency seemed to make the subject fairly distinct.

*First Class.*—No doubt in this country the morning cough to remove the accumulation of mucus, caused by nasal obstruction, post-nasal catarrh, the different forms of pharyngitis, general enlargement of vessels and glandular tissue of the pharynx, base of tongue, and upper respiratory passages, is by far the most frequent.

These conditions sometimes occur singly, but often all are present in the one patient and constitute what is called "common catarrh." They cause increased secretion, which is disposed of almost as soon as it is formed during the day, but at night it accumulates in the post-nasal space, lower part of pharynx, and superior laryngeal region. These patients, on rising in the morning, have a feeling of fullness, sometimes dryness, in the throat. It causes them little annoyance at first, but after moving about and taking breakfast their trouble begins. The act of mastication and swallowing increases the blood supply to these regions and calls into activity the normal function of the glands. The resulting secretion liquefies the mucus which has accumulated during the night and causes it, as the patient will tell you, to rise in his throat. At first there is little difficulty in getting the mucus into the mouth and expectorating it. In half an hour or so, however, the hypersecretion seems exhausted, but some thick sticky mucus still adheres to the walls of the throat. The effort to get rid of this produces a violent hawking and gagging and a succession of short coughs before it can be dislodged.

In mild cases, after the throat has been cleared in the morning, there is little annoyance for the rest of the day. In more severe cases, however, the efforts to clear the throat and post-nasal space are most distressing. They come on after every meal, after exercise, or when the atmosphere is moist, or the patient excited. The feeling that something is slipping down behind the soft palate causes a deep inspiration through the nose, followed at once by a violent cough which usually brings relief; if not, there is a succession of coughs and gagging, and relief is obtained by vomiting.

Men frequently smoke, especially a cigarette, on rising or after breakfast, as they find that by this means they are able to relieve themselves more easily and rapidly of the accumulation. Of course the smoking produces a hyperstimulation of the glands and consequent secretion, and gives temporary relief; it, however, leaves a dry and irritable feeling in the throat. To fully appreciate these symptoms one has only to be a passenger in any of our public conveyances when people are going to business in the morning. If not a sufferer himself, he will at least soon realize what a sympathetic nervous system is. This form of cough, while less dangerous than any other, is most troublesome and annoying to the patient and his friends and difficult to treat.

*Second Class.*—The cough resulting from what we call a common cold may be classed as next in frequency. The symptoms in these cases usually begin with acute rhinitis or influenza and travel down to the trachea and bronchial tubes a day or so later. Some people have their first symptoms of an approaching cold in the chest, and the throat and nose are attacked subsequently, while in others the cold begins on the chest, and does not invade the upper respiratory passages at all. In those which begin as an influenza the nasal symptoms and general febrile condition last from two to three days, when some irritation is noticed in the laryngeal region and a slight cough appears; this increases daily until about the fourth or fifth day, when the nasal symptoms will be relieved and the patient tells you that the cold is now entirely on the chest.

The cough is often severe and comes on in paroxysms, especially when speaking, eating, taking exercise, or when changing from one temperature to another, or during any excitement. There is more or less of an aching or tight feeling under the sternum, and if the person is a frequent sufferer from colds, or, as he will tell you, "catches cold easily," you find he often complains of a distinct sore spot near the ensiform cartilage. Somebody has suggested that this is caused by a semi-inflamed condition of the mucous membrane at the bifurcation of the trachea. This place, of course, receives the direct current and pressure of the air at every inspiration. The expectoration is very scanty at first and consists of white mucus. A few days later the mucus becomes more profuse, and its character will depend a good deal on the history and age of the patient and the severity of the attack.

In young people, if it is only a mild attack, the mucus is rarely profuse and only slightly yellow. In older persons, or when there is a history of repeated attacks and some chronic bronchitis or a syphilitic history, the mucus is thick and yellow in appearance and abundant. The respiration is little interfered with in young people, but in older persons, where the mucous membrane is thickened, there is a good deal of shortness of breath whenever they take cold.

*Third Class.*—We next consider the different forms of coughs encountered in the various stages of phthisis. In the early stages of the disease we are consulted for a short, dry, hacking cough, which the patient can not refer to any special cause or place; he simply has a desire to cough. It is not violent, and attention is only called to it by its persistence. It is caused, in the opinion of many physicians, by a

deposit of tubercular material around the terminal branches of the pneumogastric nerves. Its course is insidious and often so short that the physician is not consulted until the disease has advanced to another stage, when the cough becomes loose and more bronchial in character. This change in the cough is due to a catarrhal condition of the mucous membrane of the bronchial tubes and terminal bronchioles, the result of localized bronchitis. The expectoration at first is white mucus tinged with yellow; a little later it becomes thick, yellow, and tenacious, and requires a good deal of coughing to get it up. This is most troublesome during the night and in the morning—in fact, during the day there is often little coughing. The increased cough at night is probably due to the change in position of the body, as then the mucus is made to occupy different parts of the bronchial tract, and until the mucous membrane becomes accustomed to this change it resents the intrusion.

In a still later stage of this disease, when softening is going on and a portion of the lung separating, the cough is violent and continuous; also, when cavities have been formed, they fill with mucus during the night; in the morning there is violent coughing until the cavity is emptied. The coughs in the later stages of phthisis are the result of such large accumulations of mucus and necrosed tissue that they are kept up night and day and wear the patient out. The mouth and throat are frequently tender and covered with a watery mucus at this stage of the disease, which adds to the frequency and severity of the cough.

*Fourth Class.*—Many persons complain of a cough which leaves them during the warm weather, but returns on the approach of winter. This "winter cough" may be due to several conditions—viz., bronchial catarrh or thickening of the bronchial mucous membrane, chronic bronchitis, and quiescent or arrested phthisis.

There is usually a history of previous severe colds, which for several winters had been most intractable to treatment; then the patient has noticed that the cough returned with the cold weather, probably without his having any special symptoms of having taken cold.

The disease is sometimes hereditary, occurring in children whose parents have been sufferers from winter cough for years. These persons are usually pale and anæmic. All their mucous membranes are flabby and prone to catarrhal inflammations, and their recuperative powers are weak.

Women, especially blondes, suffer more frequently than men.

The initial symptoms develop in early life, when the child takes cold in the chest on the slightest change of temperature. The symptoms are slight and catarrhal in character at first, but become more marked and persistent as age advances. The mucous membrane of the lower part of the trachea and large bronchial tubes is the chief seat of the trouble. This becomes thick and tumid, and the vessels permanently enlarged. As age advances, especially in neglected cases, the tubes become dilated, and in some cases small, pouch-shaped depressions are found in the walls of the bronchial tubes and trachea. When the cough comes on, the patient has a feeling of slight oppression or wheezing over the sternal region, some aching between the

shoulders, and a sore or tender feeling through the chest, mostly on the right side.

This sore feeling is often complained of during the warm weather if there is a sudden change of temperature. Hot flashes of the face and upper extremities are common, also cold perspirations. Excitement, exercise, and sudden changes from one temperature to another aggravate the symptoms, and in some produce an asthmatical attack.

The cough in the early cases is not severe or paroxysmal, and would be called a slight bronchial cough. It is worse at night and during the early morning hours. The mucus expectorated is white and frothy. As age advances, the cough becomes violent and paroxysmal in character, and troublesome during the day as well as at night. The mucus is abundant, thick, yellow, and tenacious.

If this condition lasts for years, as it sometimes does, and nothing arrests its progress, the right heart becomes enlarged, and the general venous system sluggish. The thickened condition of the bronchial mucous membrane extends to the lung tissue and produces contraction and hardening, until both lungs are in a fibroid state, resembling, if not identical with, that of true fibroid phthisis.

This, of course, is an extreme picture, and would probably only occur in a few predisposed or neglected cases. The great majority, however, end in chronic bronchitis, which continues for years, and death may result from some other disease.

*Fifth Class; Nervous Coughs.*—This class is probably more common here than in any other country. It causes a great deal of trouble on account of its persistency and from its nature being frequently overlooked. Its nature is sometimes only discovered after many cough mixtures and other remedies have been employed for its relief. Scarcely an organ in the body has escaped the accusation of originating a nervous cough, and many of them have certainly been guilty.

In one class of cases it is the general nervous system which is at fault, while in others some particular organ originates the trouble. These coughs are characterized by short, dry hacks, which the patient takes in rapid succession. They are paroxysmal, and sometimes violent and barking in sound. During excitement they become almost continuous, and the sufferer complains of a fear of strangulation. If this continues for any time the laryngeal mucous membrane becomes red and the muscles of the neck and chest have a sore, tired feeling. Sometimes there is a dry, burning sensation through the throat. There is always a history of nervous troubles of various kinds extending over some period. Some cases entirely recover, while in others the cough extends through life and is spoken of as a habit. There is also the hemming cough of puberty, so well described recently by Sir Andrew Clarke.

It is sometimes difficult to trace the reflex form of nervous cough to its origin, and every organ may have to be examined before determining this. I think, however, when we decide that we have a reflex cough to deal with, there are usually symptoms which point to its probable origin.

*Sixth Class.*—We are all familiar with the following history: A short, plethoric person calls and tells you that

he has a bad cough, which attacks him in paroxysms, that he can not bring up any phlegm, has a full, stuffy feeling over the trachea, a little shortness of breath, and is husky at times. Appetite not good. Tongue very red or large, white, and flabby, and marked with the indentations of the teeth. Bowels probably constipated, although they may be loose. Urine high-colored, scanty, and thick. Morning nausea common. He has probably had the cough some time and taken a good many things for it without benefit. On examining this patient's throat, you find the mucous membrane of the fauces and walls of the pharynx mostly of a deep-red color, but in places it is dark blue, relaxed, and bathed in a watery mucus.

This condition extends to the laryngeal region and as far down the trachea as we can see. The congestion of these regions is produced by over-indulgence in food and alcoholic beverages. In people with a rheumatic or gouty tendency it takes very little to produce this result, while in others it comes on after a spree or steady drinking, extending over a long period.

*Treatment.*—When consulted about a cough, the first thing to decide is whether it originates in the respiratory tract or is due to some nervous disturbance.

If the former is at fault, the next decision is whether the cough is a useful or useless one, or excessive for the amount of good we might expect from it. If it is evidently doing good service, our object should be to assist it to complete its work as soon as possible. In useless coughs we consider whether they are so excessive as to require a sedative, and then direct our efforts to remove the cause. It is easy to see how important it is that all these points should be made out before we write our prescription or decide on a course of treatment. If we reply to this cry for relief by the indiscriminate use of sedatives, we may carry our patient into a dangerous position from which we can not extricate him. It is a wise course never to give opiates until you have found the cause of the cough and are satisfied that it is so excessive that it is wearing the patient out or is endangering the lung tissue. The latter is most likely to happen in the very young and in advanced life.

Some of the milder forms of sedatives may be employed with less caution, but we should always make the selection with care, as certain sedatives are specially suited for a certain class of cases and patients. In every cough resulting from acute disease an aperient will be of service, with a reduction in the quantity of nitrogenous food and a liberal supply of fluids, especially of alkaline waters.

Another general direction is the matter of dress. Probably no country in the world is subject to greater and more sudden changes than this; especially is this true of this vicinity. It would seem that in so changeable a climate the people would, as a national custom, wear next their bodies a material which would be a poor heat conductor. Some do protect themselves with woolen garments, but the vast majority wear underclothing of a material which does not retain the surface heat of the body as well as wool. Thick overcoats and other thick external garments are supposed to keep in the warmth, but this is a mistaken idea, as the warmth needs to be next the skin.

As a class, no people wear thinner boots than Americans. Women especially indulge in thin boots or slippers at times when only the thickest should be worn. Their hosiery, too, is often of the thinnest material.

It is extremely important that in persons subject to catarrhal affections of the respiratory tract special attention be given to their clothing; otherwise no amount of medication will prevent taking cold.

*The treatment of the cough* described under the first class would, of course, differ according to the cause of the accumulation of mucus or the pharyngeal irritation. When the mucous membrane of the nasal passage is at fault, as in hypertrophies, etc., there are many methods for its reduction—viz.: electric cautery, cutting, removal with snare, and various caustics. Of the latter, chromic and monochloroacetic acid are the most useful, as physicians with ordinary experience and care can use them. Monochloroacetic acid seems preferable, as it can be applied in the mild cases to the surface of the membrane, and does not make a deep sear and soon heals. When the mucous membrane is very much hypertrophied, monochloroacetic acid is also the most useful, as by submucous injection sufficient tissue can be destroyed to make the reduction permanent.

If deviated septum, spur, or any form of growth obstructs the nasal passages, only operative measures can give relief. Enlarged tonsils and hypertrophied glandular tissue at the base of the tongue must also be treated; the latter, either by the galvano-cautery or the instrument I have suggested for this purpose.

It is impossible to lay down a strict rule for the treatment of the different forms of chronic pharyngitis, but the following has given me good results. Every night spray the nose and throat, and inhale while spraying with—

℞ Acid. carbolic..... gr. ij;  
Sodii biborat..... gr. vj;  
Aquæ.....ad ʒ ij. M.

After the parts have been well cleansed with this solution, I spray them with—

℞ Liq. hydrastis..... ʒ ij;  
Benzoinol.....ad ʒ ij. M.

The following morning use spray No. 1 before breakfast and No. 2 after breakfast. Every sixth or seventh day I direct the patient to paint the post-pharyngeal wall with—

℞ Iodine..... gr. v;  
Pot. iod..... gr. x;  
Glycerin.....ad ʒ j. M.

This can easily be done with a long brush, the patient standing before a looking-glass.

Internally give one tablet sulphur co., which is composed of—

Sulphur..... gr. v;  
Cream tartar..... gr. j,

twice a day after meals. When the follicles in the pharynx are much enlarged, touch them once in two weeks with a cautery point or the nitrate-of-silver stick. Of course, every case treated in this way is not cured, but it gives very satisfactory results. To obtain success, the treatment must be carried out for from three to six months. Sum-

mer is the most suitable season for treatment. If the patient shaves, I frequently advise him to wear a beard. This may seem trivial, but it is only by the closest attention to details that a successful result can be expected.

When the pharyngeal irritation and accumulation of mucus are due to atrophic rhinitis in the stage when there is a great accumulation of dried mucus, I direct the patient to spray the nasal cavities night and morning with alkaline spray No. 1, and at night introduce, by means of a camel's-hair brush, an ointment of—

℞ Euphœn. . . . . ʒ ij;  
Ung. aquæ rosæ. . . . . ad ʒ j.

M. Ft. ungu.

During the night the ointment finds its way into the posterior nares and pharynx and keeps the mucus from getting dry and hard, and acts as a stimulant and disinfectant. After breakfast I direct the patient to blow into each nostril a small quantity of powdered euphœn.

We next consider the coughs arising from a common cold. Any one can tell when he has taken cold before any symptoms are apparent to others. This knowledge, when possible, should be treated by a good rubbing with a rough towel over the entire body, a saline purge, and as much rest as possible. In a few hours more definite symptoms appear, and the indication will then be to quiet the excitement of the central nervous system, to soothe local congestion and hyperæsthesia of the nasal mucous membrane, and arrest the discharge. There is nothing, in my opinion, which acts so promptly as the tablet triturates recommended by Dr. Lincoln. If used in the proper way, no one can fail to be impressed with their action. They consist of—

℞ Quinina sulph., }  
Camphoræ, } . . . . . āā gr. ¼;  
Ext. belladon. fl. . . . . gr. ⅛. M.

One of these should be given every fifteen minutes until there is beginning dryness of the mouth and throat, and then one every hour or two, as required. Besides this, I direct the patient to inhale from boiling water—

℞ Mentholi, }  
Camphoræ, } . . . . . āā ʒ ss.

M. Sig.: One teaspoonful to a quart of water.

Also to hold a sponge, wrung out of hot water, over the bridge of the nose. If seen early, four hours of this treatment will positively stop the sneezing and running from the nose; twenty-four hours completes the cure. If rest is not possible, I advise the patient to exercise very little, dress warmer than usual, drink little, avoid change of temperature, and continue the inhalation twice a day.

Should a bronchial irritation appear, I give—

℞ Potassii nitratis. . . . . ʒ ij;  
Ammonii bromid. . . . . ʒ iij;  
Syrup. simplicis. . . . . ʒ j;  
Aquæ . . . . . ad ʒ iij.

M. Sig.: One teaspoonful every three hours in Vichy.

If the patient is not seen until the rhinitis has been present forty-eight hours, the tablets are not so efficacious, and we have to rely more on the inhalation and ammonium-bromide mixture.

The third variety, or coughs of phthisis, requires different treatment according to the stage of the disease.

The short, dry, useless cough of the initial period of phthisis is not often troublesome enough to require treatment; when it is, one four-hundredth of a grain of sulphate of atropine, or ten drops of tinctura gelsemii, twice a day, will afford relief, or one two-hundredth of a grain of hyoscyamine is equally efficacious. Later, when there is bronchitis and considerable coughing and expectoration, creasote, taken internally and by inhalation, gives some relief. I have not had the uniform success with creasote which Dr. Beverley Robinson reports from its use. On account of its effect on the stomach, it is impossible, excepting in rare instances, to give the large doses of creasote which some observers recommend. The largest dose I have given was ten minims three times a day.

Dr. William H. Flint's creasote pill is an excellent method of administration. Hot milk, lime water, and whisky, added together, make a good vehicle. No one remedy can be relied upon for these coughs, and the greatest success may be expected from a judicious change from time to time of the remedies. Menthol, given in three-grain doses an hour after meals, is useful when the expectoration is excessive. In the latter stages, when rest is greatly disturbed, opiates are our best remedies. When the cough is due to efforts to empty a filled cavity, it should not be forgotten that the position of the patient will materially assist in doing this, and trials should be made to determine the most favorable position. Change of climate is one of our most certain remedies for the relief of these coughs, and great care must be exercised in determining what climate would be most suitable in each case.

*Treatment of Winter Coughs.*—The conditions which cause winter coughs are usually well established when the physician is consulted. The first step will be to take an inventory to determine what damage the respiratory tract has sustained, also if there is any emphysema or other lung trouble and the condition of the heart. We also inquire for any hereditary diathesis. On the result of the examination and inquiries our course of treatment will depend.

Climatic conditions influence these coughs more than anything else, and must always be considered in their treatment. A warm, dry, even temperature, free from high winds—in other words, where there is summer weather the year round—is most favorable for a cure. When this can be obtained without too great a sacrifice, it should always be taken advantage of.

Many persons, from business or other reasons, can not avail themselves of the advantages of change of climate, and we have to do the best we can for these patients at home. They should wear flannel the entire year, thin in summer and thick during the winter. Sponge the chest with cold water morning and evening, and follow it up with dry friction. Thick-soled boots should be worn, and the night air avoided as much as possible. Cold sleeping-rooms and breathing through the mouth must be guarded against; also sudden changes of temperature. Should these precautionary measures prove useless and the sufferer finds he has taken cold, or that the cough is simply returning, we must

endeavor to give as much relief as possible. This is best done by daily inhalations of vaporized Dobell's solution, or some other soothing vapor. The whole list of balsams are more or less beneficial, but their effect on the stomach is so disastrous that they can not be taken for any length of time. Each case will require a special selection of drugs. Terpin hydrate and creasote have given me the most satisfaction. The soreness and aching over the trachea and sternum are greatly benefited by—

℞ Olei sinapis sem. . . . . ℥x;  
Spt. vin. rect. . . . . ad  $\frac{3}{4}$  ss.

M. Sig.: Apply with camel's-hair brush twice a day.

Attention must be paid to the physical condition, and the organs kept in the best possible health.

Success with these cases depends more on the general management of the patient and persistency in treatment than on internal administration of drugs directed to the cough.

Nervous coughs must be treated according to their kind and cause. The accompanying symptoms and general history will decide this. When there is a local or reflex cause, the treatment must be directed to allay or remove the irritation. In one case I removed a piece of coal, weighing five grains, which had been imbedded in the external auditory canal against the tympanum for thirteen years. This cured the cough and asthmatical attacks from which the patient had suffered.

Abrasions of the nasal mucous membrane and also pressure in the nose frequently causes reflex coughs. It is usually not difficult to relieve these coughs, if the diagnosis has been correct.

The neurotic cough in girls with chlorosis and boys at the age of puberty is successfully treated with iron and sulphate of magnesia. Judicious bathing, exercise, and friction of the skin must also be employed. Counter-irritation in the ovarian region is sometimes useful, and a sea voyage may be necessary in some cases.

In adults, when the cough is due to a general neurasthenic condition, many plans may be tried without success. Tonics, combined with prolonged rest or a sea voyage, is the most satisfactory. Oxalate of cerium, if kept up for a long time, has relieved some cases. When the cough seems to have become a habit, there is little use of trying to stop it.

The coughs resulting from excessive indulgence in food and alcoholic beverages are benefited by a moderation of the cause.

Aperients and plenty of alkalies and alkaline drinks must be given. Spraying the throat twice a day with—

℞ Acid carbol. . . . . gr. j;  
Liq. hydrastis . . . . . ʒ j;  
Benzoinol. . . . . ad  $\frac{3}{4}$  j. M.—

allays the irritation. If there is any rheumatic or gouty history, it must receive attention in the treatment.

22 EAST FORTY-SECOND STREET.

**The Manhattan Dispensary.**—A new hospital building, at West One Hundred and Thirty-first Street and Tenth Avenue, was opened to inspection by an invited company on Thursday afternoon of this week.

## THE PHYSICIAN'S RESPONSIBILITY IN THE TREATMENT OF FRACTURES.\*

By GEORGE W. KING, M. D.,  
SURGEON TO THE MONTANA COMPANY (LIMITED), HELENA.

EVERY one who practices the healing art is expected to assume the responsibility of treating fractures; and no matter how serious or complicated the injuries, or under what adverse circumstances they occur, the exacting public require him to conduct his cases to a successful issue in every instance.

Accidents involving fractures are of common occurrence; and the majority of these cases naturally fall into the hands of the nearest or most available physician. He can not avoid them if he would. If he attempts to shirk the responsibility, when called upon to take charge of a broken limb, his skill in other lines of practice is questioned, and the inference quickly drawn that he is not a safe man to trust in any event. There is, therefore, no choice upon the physician's part—he must do the best he can, even though he knows he will be held personally liable for any defect in the healing of the injuries he undertakes to treat.

While the management of broken bones is usually regarded by the non-professional as a very simple affair, it is in reality one of the most difficult duties we have to perform. There are no other class of cases which furnish so many suits for malpractice, none in which the physician is so unjustly persecuted. There is certainly a wrong sentiment prevailing in every community in regard to the extent of the physician's liability. Who is to blame for this error? The physician himself, in so far as he fails to deal candidly with his patient, is to blame for promising to do what the ablest surgeons in the profession, with all the facilities at their command, have declared their inability to do—to blame for claiming more than the resources of his art will warrant. The consequences of so unwise a course are injurious in the extreme.

The patient who has been deceived by his physician in regard to the prognosis of his case becomes dissatisfied, and believes that he has been unskillfully treated, and very likely seeks advice elsewhere, and is probably told that better results could have been obtained by proper treatment. Are we not all too ready to encourage the public in believing that perfect results ought to be obtained after simple fracture, and that anything short of a complete cure is the physician's fault?

This belief, shared in a measure by physicians themselves, imposes an unnecessary hardship upon us all. When we come to understand, and are willing to admit, that deformity, with more or less impairment of function, is a common result after simple fracture under the most skillful treatment, less will be expected of us and impossible cures no longer required at our hands.

Unfortunately, in the treatment of fractures, the deficiencies of our art become more apparent than in other departments of our work. A failure to cure diseased condi-

\* Abstract of a paper read before the Medical Association of Montana, May 29, 1891.

tions of the human system by medical means is never considered sufficient ground for damages against the physician; but whoever is so unfortunate in his practice as to get a badly deformed limb, is doomed to be ever shadowed by its possessor (for he never dies, but remains waiting and watching in the hope that the doctor will accumulate property enough to make it worth while to bring a suit for damages).

What can the surgeon really do in the treatment of fractures? What are the limitations of his art? These are important questions, and have a direct bearing upon the physician's responsibility in law. Men of limited experience, who may have had the good fortune to treat a few cases of simple fracture, without displacement, and who have obtained good results, are misled by their success, and imagine themselves authorities upon the subject; and by their ignorance of the real conditions to be met with in more complicated cases, are capable of doing harm when they attempt to dictate to juries what should have been the proper treatment in a given case. Such evidence is manifestly incompetent; but it often has greater weight with the court and jury than the highest authorities in the land.

It is not to the ignorant and inexperienced that we look for guidance, but to those men whose opportunities for observing and experience in treating fractures give them the right to be heard. They all agree that shortening, with some deformity, after the fracture of long bones is the rule in practice, regardless of any of the plans of treatment now in use. Such statements from recognized authorities indicate what we may expect under the most improved methods of treatment, and we have only to refer to our individual experiences to confirm this statement in full.

It is certainly discouraging, after applying all the improved methods, to find that, somehow or other, broken limbs will unite with deformity when we have done our best to keep them straight, and, after all our care and anxiety, very likely involve us in costly litigation, because we were unable to restore the part to its original perfection. Were it possible to join broken bones as the artisan does wood and steel, by mathematical rule, there might be some excuse for so rigid an enforcement of the law. But instead of that we have a human being to manage, diseased conditions to treat, muscular action to overcome—conditions that in many instances are absolutely beyond our control. The more common deformities following fractures, such as are liable to occur in the practice of any one, are the cases that are paraded in court and exhibited to juries to enlist their sympathies and influence them to return a verdict against the physician.

Perfect results are seldom obtained by any or all methods now in use; but the law requires impossibilities of no man, only a reasonable performance of what he undertakes. The same rule applies to lawyers, engineers, machinists, and all other classes who transact business requiring special skill. The requirements of the law, as applied to the physician, are: First, that he possess "that reasonable degree of learning, skill, and experience ordinarily possessed by others of his profession"; second, that he use ordinary care in the treatment of the cases committed to him; third, that he use his best judgment in matters of doubt. He is not

responsible for want of success unless it is proved to result from want of ordinary skill or ordinary care. He is not responsible for errors in judgment or mere mistakes in matters of reasonable doubt.

These are the principles of common law, and if strictly adhered to would protect the medical profession from unjust and malicious persecution. We admit the fundamental principles of the law, but have a right to complain at the unjust discrimination in its practical application to physicians. Individuals of all other trades or professions can be guilty of negligence or want of skill, and are never punished. Should disease invade your home by reason of defective plumbing, should your carriage collapse suddenly from faulty construction and cripple you for life, would you expect to recover damages? Certainly not; such a case would be ruled out of court. Quacks and impostors ply their vocation in every community unmolested, while the skilled physician, who has spent years of study to qualify himself for his work, is held strictly accountable for every act, and his treatment overhauled in a court of justice upon the slightest provocation.

The facilities for bringing suit for malpractice are so great that no physician, however eminent, is safe. A pauper, a hungry attorney, and a quack doctor can get a case into court without the expenditure of a dollar.

The whole system by which the physician is tried is prejudicial to his interests. The jury is usually composed of ordinary men who think only upon ordinary subjects, and can not be expected to judge correctly upon matters pertaining to medical science. The attorney for the prosecution summons as experts those who will swear for his side, regardless of their standing in the profession—men who care nothing for truth or science, but who can, with assumed wisdom, assert their opinions with a positiveness that, in spite of all evidence to the contrary, is apt to secure a verdict for the plaintiff.

It is certainly an unsatisfactory application of law that compels the members of an honorable profession to suffer the indignity of being confronted in courts of law by ignorant pretenders, their good names tarnished, and the earnings of a lifetime squandered in defending themselves.

How can we, as an association, remedy this evil, or, at least, secure a better recognition of our rights? I believe that by united effort much may be accomplished. Do you know that every case of malpractice that comes into court is instigated by physicians or so-called doctors, who really prosecute the case for the plaintiff? This ought not to be; rather should each one strive to elevate the profession to which he belongs, and gladly lay aside all local jealousies to rally to the aid of a fellow-physician when unjustly assailed.

During the past year a verdict has been obtained against a member of this association. Of its injustice there is not the slightest doubt. Competent physicians testified as to the correctness of the treatment. There was no proof of a want of ordinary care and skill. Having established his innocence of these charges, nothing more in the line of defense is possible. The law requires no more, and yet the jury returned for the plaintiff, with damages of \$500. This is the kind of justice that physicians are con-

stantly receiving in our courts. Some modification in the system of trying malpractice suits is imperatively demanded. A board of arbitration, consisting of physicians and attorneys, men of scientific attainments, and, above all things, honest, is the only proper tribunal. Legislation requiring plaintiff to give bonds for costs is only a matter of simple justice to the physician. A committee, composed of members of the association who are willing to devote the time necessary to becoming thoroughly conversant with medico-legal technicalities, and to assist in defending those who require such aid, would prove much more satisfactory than the bungling manner in which these suits are usually conducted.

To one engaged in the unequal struggle of maintaining his right before the law, the sympathy of his professional brethren becomes a grateful assurance. It should be freely given to every worthy physician. Those who practice dishonorably, whose ways are dark and mysterious, have no claim upon us. These are the men who bring discredit upon the profession, and by their sharp methods create a feeling of distrust against all physicians.

In "the great conflict that is constantly going on between science and ignorance," it is to be hoped that the Medical Association of Montana will take the aggressive, and endeavor to protect the people and the profession by enforcing a higher culture that shall make the distinction so great that all may recognize the true physician from the impostor.

## HOT BLANKET PACKS IN THE TREATMENT OF FEVERS.

BY W. W. BREMNER, M. D.

THERE has lately been a considerable amount of discussion in regard to the Brandt treatment of typhoid fever, by which a patient is put into a bath of water of a temperature of 70° F., and, while the reported results seem fairly favorable, yet the treatment is apparently harsh and often difficult of application.

As, week by week, the great number of febrile diseases is reported by the Health Department, and with such a large proportion of deaths, I have felt impelled to bring before the profession a simple method of treatment for typhoid fever and any other febrile disease (especially scarlet fever and measles in children) which has been very successful in my hands and which is perfectly safe, comfortable, and easy of application, either in private or in hospital practice.

Take a blanket, just large enough to completely envelop the patient; fold it lengthwise twice; then roll it up into a moderately tight roll. Boil until dissolved two ounces of good soap in two quarts of water. Pour the boiling solution slowly into the center of the ends of the roll of blanket, stopping at intervals to clap the outside of the blanket to facilitate its thorough saturation. Either a cot beside the patient's bed, or half of the bed on which he lies, should be prepared by laying on it a Mackintosh sheet, over which is placed a large double blanket dry, so arranged as to come half-way up on the pillow, and thus be ready to completely and thoroughly surround the patient's neck. The patient should be undressed and have a loose blanket thrown over

him. All being in readiness, the roll should be laid at the bottom of the bed and quickly unrolled from below upward and spread out on the dry blanket. In about two or three seconds, judging the heat by the hand, place the patient upon the center of the hot wet blanket; two ordinary attendants can easily do this even when an adult is delirious. Wrap him up, with the arms inclosed, from both sides; first with the wet blanket and then with the double dry one, taking great care to make the dry one fit closely round the neck, and fastening it in position with a safety-pin. The feet must be well tucked up, and, if they are inclined to be cold, a hot-water bottle should be applied and inclosed in the outer coverings. If the room is cold, another quilt may be thrown over these coverings. A handkerchief squeezed out of cold water should be placed on the temples and renewed every few minutes, or an ice-bag applied to the whole head. The patient should be supplied with cold water to drink as often as desired.

The pack should be continued from one to two hours, according to the state of the temperature and the feelings of the patient; children often fall asleep during the application. The temperature will usually fall after it has been applied a little time, and, if the patient is delirious or comatose, intelligence will return more or less completely. The pack should be repeated twice or thrice daily until the temperature falls permanently below 101° F. When it is removed, the patient should be gently rubbed with a soft towel and replaced in the ordinary bedding.

The medicinal treatment in typhoid consisted in small doses of well-diluted hydrochloric acid, and the treatment of any symptoms that arose according to their indications: occasionally, when the diarrhoea was very troublesome, copious enemata of warm water were given once daily with marked benefit. In some cases the temperature seemed to be very little affected, but the same beneficial results followed. One very severe case of typhoid fever treated in this way in 1888 was that of a child fourteen months old. The case was given up by one of the leading physicians. The temperature was 105° F., and the child was comatose. The first pack was put on very wet and left on for three hours; it reduced the temperature to normal, and restored the child to sensibility. In about five hours the temperature again rose to 105° F., and insensibility returned; three packs daily, averaging two hours each, were given for eleven days before the temperature was reduced to stay below 101°. This child made a good recovery.

In scarlet fever and measles, to commence their treatment by one or two packs of this kind generally seems to quite break up the disease, and in a large private practice I can only recollect one death from scarlet fever during several years, when treated in this way, though in some epidemics there were very many deaths in the same district among children not so treated. This method of treatment has all the advantages of the cold-water applications without any of their drawbacks. There is no shock to the patients, and children have no fear of it; in fact, rather seem to enjoy it. The temperature can be lowered just as certainly as by the application of cold water, evaporation takes place from such a large surface.

D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MAY 28, 1892.

ASCENDING GONORRHOEA IN WOMEN.

If gonorrhœa in the male still presents many points upon which pathologists differ, the same affection in the female scarcely possesses a point upon which they agree. Ever since the promulgation of Noeggerath's famous dictum as to the relation existing between pelvic affections in women and latent gonorrhœa in men, pathologists have busied themselves in the attempt to trace the gonococcus of Neisser from its entrance into the vagina up to the uterus, the Fallopian tubes, the ovaries, and the pelvic peritonæum, and to explain the pathological processes found in these various organs as due to its presence. Many obstacles have surrounded these investigations, and some of them have appeared insurmountable. For instance, it has generally been held that the gonococcus had not the power of penetrating into pavement epithelium, and consequently had no power of exciting disease in serous structures. To explain, therefore, the pathological changes found in the peritonæum covering the tubes in cases of pyosalpinx undoubtedly due to the gonococcus, as shown by its presence in the tubes, it was assumed that there was a "mixed infection," and that *Staphylococcus aureus* and *Streptococcus pyogenes* were the pathogenic factors of the peritoneal affection. Experimental researches on the lower animals, which are usually of such great aid in similar investigations, were not resorted to, because it was known that the mucous membrane of the lower animals was not susceptible to the action of the gonococcus. The same immunity was inferred to exist in the case of the peritonæum.

If we are to accept Wertheim's investigations, published in a recent number of the *Archiv für Gynäkologie*, this inference was erroneous. He has succeeded quite readily in exciting peritonitis in mice and guinea-pigs by injecting pure cultures of Neisser's gonococcus into the abdominal cavity. Rabbits and rats were found to be less susceptible, and dogs quite insusceptible. In two cases, after laparotomy done on women, Wertheim found gonococci in the tubes, the ovaries, and the peritoneal tissues. Previous to that, no one had succeeded in finding gonococci in the inflammatory products of the peritonæum. The gonococci, according to this observer, pass to the peritonæum either directly through the walls of the Fallopian tubes, or through their abdominal openings. He has detected gonococci in every layer of the tubal tissues, and thinks he is justified in assuming that they may pass directly through these tissues to the peritoneal surface. It has also been hitherto maintained that the gonococcus was incapable of exciting inflammatory action in connective tissue. Wertheim's researches on the lower animals contradict this assertion. He has succeeded in several instances in setting up a virulent in-

flammation by injecting pure cultures of the gonococcus directly into the connective tissue of the lower animals experimented upon. In a few cases of pyosalpinx and ovarian abscess gonococci were the only bacteria found. On the strength of his experiments and investigations, Wertheim concludes that gonorrhœa in women does ascend to the uterus, to the tubes, to the ovaries, to the peritonæum, and into the tissues of the broad ligaments.

MINOR PARAGRAPHS.

"SUNDOWNERS."

This term, as our readers have been informed, is applied in Washington to physicians who, being employed during the day-time in some of the Government offices, devote their evenings to what medical practice they may succeed in picking up. These gentlemen are accused of "cutting rates," and in that and other ways they seem to have incurred the hostility of the other medical practitioners of the city. Perhaps as a consequence of this feeling, the Medical Association of the District of Columbia, we learn from the Washington newspapers, has incorporated in its by-laws the following declaration: "No graduate of medicine shall be eligible to membership in the association who shall not devote his entire time to the practice of medicine." The association has, of course, a perfect right to limit its membership in any such way as this, but it seems to us that the limitation, if strictly carried out, will deprive the association of the company of many gentlemen who would be an ornament to any medical body, and it is quite imaginable that some of the genuine "sundown doctors" might be of the number.

OIL OF EUCALYPTUS.

This oil has grown into such great demand in Europe that over twenty thousand pounds were exported from California in 1891. A sketch of the rather remarkable history of this commodity is given in the *Independent*, which dates the beginning of the cultivation of the tree in California from 1869. In that year fifty acres, near Haywards, were planted, chiefly for lumber purposes. Since then enormous numbers of the tree have been planted. About ten years ago the discovery was made that a decoction of the leaves of eucalyptus had the property of removing the scales of incrustation from boilers. While the engineers were preparing their anti-scale fluid they appeared to be cured of their ailments, such as bronchitis and asthma, and they started a factory or works for the extraction of the oil at San Lorenzo. From this, as a beginning, a very considerable industry has sprung up.

METHYLENE BLUE IN MALARIAL FEVER.

In the *Bulletin of the Johns Hopkins Hospital* for May there is a report by Dr. W. S. Thayer of seven cases of malarial fever treated with methylene blue. He concludes that it has a definite action in the disease, accomplishing the destruction of the specific organism, though less efficacious than quinine and failing in many cases in which the latter drug is efficacious. Methylene blue acts rapidly, the chills disappearing, and the temperature falling to normal in the first four or five days, though if a sufficient number of organisms resist the drug they develop again rapidly during its administration, and the malarial symptoms return. The drug seems to have no advantage over quinine that would warrant its further employment in malarial fever.

## THE UNIVERSITY OF VIRGINIA.

THE annual circular of this institution shows the organization of a summer faculty, for the private instruction of intending medical students and practitioners who desire to refresh their knowledge during the months of July and August. The courses of study are also arranged to suit the needs of those who are about to undergo an examination for the army or navy medical staff. The summer instruction is carried on both by lecture and by laboratory work.

## THE SUDDEN DEATH OF A BICYCLIST.

A YOUNG Englishman is reported to have died recently of cardiac angina, after overstrain in riding his "wheel." He had shortly before covered forty miles in very quick time, and was in training for a competitive or record-breaking contest; so that the competition rather than the bicycle must be held accountable for his death.

## ITEMS, ETC.

The **Massachusetts Medical Society** will hold its one hundred and eleventh annual meeting in Boston on Tuesday and Wednesday, June 7th and 8th, under the presidency of Dr. Amos H. Johnson, of Salem. The programme gives the following titles:

The Relations of Bacteria to Influenza, by Dr. Henry Jackson, of Boston; Pneumonia in the Recent Epidemics, by Dr. W. E. Fay, of Boston; The Nervous and Mental Sequelæ of Influenza, by Dr. P. C. Knapp, of Boston; A Revision of the Medical Nomenclature employed in the Vital Statistics of Massachusetts, by Dr. S. W. Abbott, of Wakefield; Bacteriological and Clinical Investigations into the New Antiseptic Dermatol, by Dr. A. K. Stone, of Boston; The Diagnosis and Treatment of Pott's Fracture of the Ankle, by Dr. L. A. Stimson, of New York; Acute Intestinal Obstruction (the Symptoms and Diagnosis, by Dr. F. C. Shattuck; the Surgical Aspects, by Dr. John Homans, Dr. J. C. Warren, Dr. G. W. Gay, Dr. M. H. Richardson, Dr. J. C. Irish, and Dr. A. T. Cabot); Résumé of 100 Cases at the Knowles Maternity, Worcester, by Dr. G. O. Ward, of Worcester; Alexander's Operation, by Dr. W. M. Conant, of Boston; Hydatidiform Moles, by Dr. G. A. Craigen, of Boston; The Treatment of Inflammatory Diseases of the Falloppian Tubes, with Cases, by Dr. Edward Reynolds, of Boston; the Shattuck Lecture, by Dr. J. F. Alleyne Adams, of Pittsfield; The General Practitioner as a Gynæcologist, by Dr. W. H. Pierce, of Bernardston; An Outbreak of Trichinosis in Colerain, by Dr. F. H. Drew, of Shelburne Falls; The Treatment of Compound Fractures by Modern Methods, with a Demonstration of "putting up" adapted to Private Practice, by Dr. H. L. Burrell and Dr. E. W. Dwight, of Boston; and The Annual Discourse, by Dr. Frank W. Draper, of Boston.

The **Medical Society of the County of New York**.—The programme for the meeting of Monday evening, May 23d, included a paper on Plaster Models of Skin Diseases and of Pathological Objects, by Dr. W. S. Gottheil; a Note on the Treatment of Cholera, by Dr. C. L. Dana; and a paper on Infant Feeding, with Special Reference to Hot Weather, by Dr. H. D. Chapin.

The **New York Dermatological Society**.—At the annual meeting, on Tuesday evening of this week, officers for the ensuing year were elected as follows: President, Dr. George T. Elliot; secretary and treasurer, Dr. Hermann G. Klotz; members of the executive committee, Dr. George H. Fox, Dr. Robert W. Taylor, and Dr. Daniel Lewis.

A **Monument to Dr. Coste**, according to the *Union médicale*, was recently inaugurated in a little village of the department of the Ain. Our contemporary does not mention which Coste it is whose memory is thus honored, but it speaks of him as the friend of Voltaire, of Choiseul, of Washington, and of Goujon. From this we infer that it is Jean François, who figured in the American Revolution, and not the great embryologist.

The **Death of Dr. John K. Ambrose**, formerly of Staten Island and Brooklyn, took place at his home on Madison Avenue on May 17th. He was a native of Ireland, and about fifty-six years old. He was a graduate of the Long Island Medical College. He served as coroner in Richmond County for six years. Until quite recently he was a medical sanitary inspector of the board of health.

The **Death of Professor Wilhelm Braune, of Leipsic**, is announced in the *Lancet* as having taken place on the 29th of April. He was in his sixty-first year.

The **Death of Dr. Pliny Earle**, of Northampton, Mass., on the 17th inst., removes one of the foremost of American alienists. He was born at Leicester in 1809. In 1837 he was graduated from the University of Pennsylvania. He entered into practice in Philadelphia, but soon afterward accepted the post of resident physician to the Friends' Asylum for the Insane at Frankford. In 1844 he was called to the Bloomingdale Asylum, and a few years later became visiting physician to the county buildings on Blackwell's Island. In 1848 he published his well-known history and statistics of Bloomingdale Asylum. In 1864 he received his appointment as superintendent of the State Asylum at Northampton, where he made a name for himself in psychopathic medicine wider than his State and country. His contributions to medical literature have been numerous, chiefly but not solely in the field of the treatment of the insane. Many of his papers were published in the *American Journal of Insanity* and the *American Journal of the Medical Sciences*. Some of these papers have been republished in book and pamphlet forms. He was a member of many scientific societies at home and abroad, also president of the New England Psychological Society. He was one of the early members of the American Medical Association.

**Change of Address**.—Dr. Horatio F. Wood, to the Masonic Temple, corner of State and Randolph Streets, Chicago.

**Army Intelligence**.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 15 to May 21, 1892:*

LIPPITT, WILLIAM F., Jr., First Lieutenant and Assistant Surgeon, upon being relieved from duty at Fort McPherson, Georgia, will report in person to the commanding officer, Camp Eagle Pass, Texas, for duty at that post, relieving RAFFERTY, OGDEN, First Lieutenant and Assistant Surgeon. First Lieutenant OGDEN Rafferty, on being relieved by First Lieutenant Lippitt, Jr., will report in person to the commanding officer, Alcatraz Island, Cal., for duty at that post.

BAILY, JOSEPH C., Colonel and Surgeon, is granted leave of absence for six months, on surgeon's certificate of disability, with permission to leave the Department of Texas.

PURVIANCE, WILLIAM E., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer, Jefferson Barracks, Missouri, for duty at that post.

WINTER, FRANCIS A., First Lieutenant and Assistant Surgeon, is relieved from duty at Jefferson Barracks, Missouri, and will report in person to the commanding officer, Fort Riley, Kansas, for duty at that post.

HUNTINGTON, DAVID L., Major and Surgeon, is relieved from duty in New York city, to take effect on the final adjournment of the Army Medical Board, and will then proceed to Los Angeles, Cal., and report in person to the commanding general, Department of Arizona, for duty as Medical Director of that department, relieving SMITH, JOSEPH R., Colonel and Surgeon. Colonel Smith, on being relieved by Major Huntington, will proceed to San Francisco, Cal., and report in person to the commanding general, Department of California, for duty as medical director of that department.

A board of medical officers, to consist of FORWOOD, WILLIAM H., Lieutenant-Colonel and Surgeon; GIBSON, JOSEPH R., Major and Surgeon; and TERRILL, HENRY S., Captain and Assistant Surgeon, is appointed to meet at West Point, N. Y., June 1, 1892, or as soon thereafter as practicable, for the physical examination of the cadets of the graduating class at the U. S. Military Academy, and such other cadets of

the Academy and candidates for admission thereto as may be ordered before it.

- KIMBALL, JAMES P., Major and Surgeon. The leave of absence granted is extended one month.
- SHAW, HENRY A., First Lieutenant and Assistant Surgeon, is granted leave of absence for two months, to take effect June 25, 1892, or as soon thereafter as his services can be spared.
- SETER, WILLIAM N., Assistant Surgeon, to be Assistant Surgeon with the rank of Captain, May 16, 1892, after five years' service, in accordance with the act of June 23, 1874.
- DE WITT, THEODORE F., First Lieutenant and Assistant Surgeon, resigned May 16, 1892.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending May 21, 1892:*

- BABIN, H. J., Surgeon, and DRENNAN, M. C., Passed Assistant Surgeon, ordered to Naval Academy to examine the physical condition of candidates for admission to Naval Academy.
- BIDDLE, CLEMENT, Passed Assistant Surgeon. Ordered to Marine Rendezvous, Philadelphia, Pa.
- ECKSTEIN, H. C., Surgeon. Detached from Marine Rendezvous, Philadelphia, Pa., and to wait orders.
- WELLS, HOWARD, Surgeon. Ordered to the training-ship Portsmouth.
- STOUGHTON, JAMES, Assistant Surgeon. Detached from the Portsmouth and ordered to the Constellation.
- MARSTELLER, E. H., Passed Assistant Surgeon. Detached from the Naval Academy and ordered to the Constellation.
- FIELD, JAMES G., Assistant Surgeon. Granted one year's sick leave.
- HORWITZ, P. J., Medical Director (retired). Granted six months' leave to go abroad.
- LOVERING, P. A., Surgeon. Detached from the U. S. Steamer Philadelphia and granted two months' leave of absence.
- CRANDALL, R. P., Passed Assistant Surgeon. Detached from the Naval Laboratory, Brooklyn, N. Y., and ordered to the U. S. Steamer Philadelphia.
- BOGERT, E. S., Jr., Assistant Surgeon. Detached from the Coast Survey Steamer Blake and ordered to the Naval Laboratory, Brooklyn, N. Y.
- GUTHRIE, J. A., Assistant Surgeon. Detached from Port Royal Station, S. C., and ordered to the Coast Survey Steamer Blake.
- ECKSTEIN, H. C., Surgeon. Granted leave of absence for six months.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the two weeks ending May 21, 1892:*

- MURRAY, R. D., Surgeon. Granted leave of absence for fifteen days. May 14, 1892.
- HAMILTON, J. B., Surgeon. Granted leave of absence for eleven days. May 20, 1892.
- GASSAWAY, J. M., Surgeon. Granted leave of absence for ten days. May 10, 1892.
- GODFREY, JOHN, Surgeon. When relieved as Medical Inspector of Immigrants, to resume command of station at New York. May 11, 1892.
- IRWIN, FAIRFAX, Surgeon. To proceed to New Bedford, Mass., on special duty. May 17, 1892.
- CARTER, H. R., Surgeon. To proceed to Gallipolis, Ohio, on special duty. May 18, 1892.
- WHEELER, W. A., Surgeon. Detailed as Medical Inspector of Immigrants, port of New York. May 11, 1892.
- BANKS, C. E., Passed Assistant Surgeon. To assume command of service at Portland, Maine. May 11, 1892.
- DEVAN, S. C., Passed Assistant Surgeon. To assume command of service at Norfolk, Va. May 11, 1892.
- PERRY, T. B., Passed Assistant Surgeon. To assume charge of Cape Charles Quarantine Station. May 14, 1892.
- WOODWARD, R. M., Passed Assistant Surgeon. Granted leave of absence for five days. May 16, 1892.
- VAUGHAN, G. T., Passed Assistant Surgeon. Detailed as recorder of Board for the physical examination of candidates, Revenue-Marine Service. May 9, 1892.

WERTENBAKER, C. P., Assistant Surgeon. Granted leave of absence for seven days. May 10, 1892.

HOUGHTON, E. R., Assistant Surgeon. To assume command of service at Vineyard Haven, Mass. May 11, 1892.

**Society Meetings for the Coming Week:**

TUESDAY, *May 31st*: American Surgical Association (first day—Boston); Medical Association of Central New York (Syracuse); Medical Societies of the Counties of Queens (annual—Mineola) and Rockland (annual), N. Y.; Boston Society of Medical Sciences (private).

WEDNESDAY, *June 1st*: American Surgical Association (second day); Society of the Alumni of Bellevue Hospital; Harlem Medical Association of the City of New York; Medical Microscopical Society of Brooklyn; Medical Societies of the Counties of Cattaraugus (annual) and Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Orleans, Vt., County Medical Society (annual); Bridgeport, Conn., Medical Association; Philadelphia County Medical Society.

THURSDAY, *June 2d*: State Medical Society of Arkansas (first day—Little Rock); Oregon State Medical Society (first day—Portland); Rhode Island Medical Society (first day—Providence); American Surgical Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington).

FRIDAY, *June 3d*: State Medical Society of Arkansas (second day); Oregon State Medical Society (second day); Rhode Island Medical Society (second day); Baltimore Clinical Society.

SATURDAY, *June 4th*: American Academy of Medicine (Detroit); State Medical Society of Arkansas (third day); Oregon State Medical Society (third day); Clinical Society of the New York Post-graduate Medical School and Hospital; Miller's River, Mass., Medical Society; Manhattan Medical and Surgical Society (private).

## Proceedings of Societies.

### NEW YORK ACADEMY OF MEDICINE.

SECTION IN ORTHOPÆDIC SURGERY.

*Meeting of April 15, 1892.*

Dr. HENRY LING TAYLOR, Chairman.

**Hip-joint Disease.**—Dr. LEWIS A. SAYRE said that in his paper read at the last meeting (see page 477) he had referred to a case of hip disease that he had seen in consultation with Sir James Paget and Mr. Adams, of London, in which it had generally been considered that recovery could not take place without ankylosis and deformity. He was fortunate in having the opportunity of presenting the patient at this meeting. The man could place the feet on a table, could squat down, and, in fact, could perform every motion so well that it was difficult to tell which had been the diseased hip.

**The Effect of Persistent Motion.**—Dr. JOHN RIDLON exhibited a girl, nine years old, who had come to him at the Vanderbilt Clinic on April 23d. Eight months previously she had received an injury to the right elbow, which was diagnosed as a "fracture of the coronoid process of the ulna, and a dislocation backward of the radius and ulna." She was attended by a well-qualified practitioner. The arm was immobilized for

about four weeks, and then passive motion was begun. Twice daily the forearm was flexed and extended on the arm to the limits of tolerance, and twice weekly, under an anæsthetic, the forearm was flexed and extended to the normal limits of motion. This treatment was faithfully continued for seven months, during which time the range of motion gradually became more restricted, the joint more and more swollen and more painful under the attempts at motion. Examination showed the forearm flexed on the arm to a right angle, much swelling about the joint, enlargement of superficial veins, and atrophy of the muscles of the arm and forearm. The swelling had a pulpy feel, but no point of fluctuation could be detected. The bony points were so obscured that the exact nature of the injury could not be determined. There was no motion at the joint, and attempts at motion caused pain and intense muscular spasm. In the treatment adopted the head was bent down, and the wrist put into a "halter" made of a roller bandage knotted around the wrist and neck. The slack of this was taken up as the rigidity yielded, and at the end of two weeks the joint could be flexed completely. In this position the joint was held without motion being once permitted or tested for eleven months. The pain disappeared, the swelling gradually subsided, and when the halter was removed there was found to be free, painless motion from a right angle to normal flexion. Since then there had been no treatment, and the range of motion in the direction of extension was gradually increasing.

Dr. W. R. TOWNSEND said that this girl had been brought to the Hospital for the Ruptured and Crippled about two years ago by her attending physician, who said that passive motion had been made under ether anæsthesia about three times a week since the fracture to prevent ankylosis. Dr. W. T. Bull, who had seen the case in consultation, had agreed with the speaker in advising rest. The attending physician dissented from this view, but finally said he was willing to give the joint rest for a limited time if he was relieved from all responsibility as to the result. The case was accordingly treated in the hospital with a plaster-of-Paris splint for about four weeks, when the mother objected to a continuance of this treatment. Dr. Bull again saw the case in consultation, and the opinion was then expressed that there was a beginning osteitis, and that if motion was kept up, the child would undoubtedly have a stiff elbow. The patient and doctor dissented again, and wished passive motion made; so she was then discharged from the hospital outpatient department.

Dr. S. KERON said that if the arm was moved beyond a certain point, especially in rotation, there was reflex spasm, and he thought there was still some active disease in the elbow joint. He asked if the halter allowed of pronation and supination.

Dr. RIDLON replied that the halter did not prevent these motions, but, so far as his experience with it had gone, when properly applied under the clothes, the children, as a matter of fact, did not attempt to make these motions.

**A Case for Diagnosis** was presented by Dr. RIDLON. A man, thirty-four years old, had come to him at the Vanderbilt Clinic on February 15th. For two weeks he had been stooping and stiff in the lumbar spine, with pain in the back and lower abdomen, and, at times, down the front of the thighs. Seven years before, he had had a similar attack, at which time, after suffering for four weeks, he went to the dispensary of an orthopædic institution in New York, where the diagnosis was made of Pott's disease and a Taylor spinal brace applied. He remained in bed for two months, wearing the brace, but without any relief. He was then admitted into the St. Francis Hospital, where a blister was applied, and the pain was immediately relieved. At the end of two weeks he was quite well again, and

had remained so up to the present attack. Examination revealed the whole lumbar spine curved backward and rigid; there was psoas contraction on the left side, but none on the right; and there was a doubtful fullness in the left iliac fossa. He was treated with antirrhematic remedies, and soon showed improvement, and in the course of a few weeks felt entirely well. There was now no spinal curvature, no rigidity, no psoas contraction, and the patient was quite well, except that at times after long sitting over a bench at his work he felt some stiffness of the back.

**An Inexpensive Head Support.**—Dr. ROYAL WHITMAN showed a support that he had devised for a child with mid-dorsal disease, in whom there was a tendency for the shoulders and the whole body to droop forward. The support consisted of a curved piece of steel attached to the back of the brace used in connection with lateral pads for holding the shoulders back, a form of apparatus which he had already exhibited and described.

Dr. V. P. GIBNEY then exhibited a series of operative cases, including one of ankylosis of the hip after typhoid fever, one of excision of one hip in a case of double hip disease where sacro-iliac disease was first diagnosticated, one of excision of the hip, a case for diagnosis (probably one of subacute rheumatism), and one of atonic knock-knee.

**Some of the Indications for Operative Interference in Orthopædic Surgery.**—A paper with this title was read by Dr. GIBNEY. The paper dealt first with the range of orthopædic surgery as held by the majority of surgeons practicing this specialty throughout the world. The author commented on the brilliant results obtained by general surgeons in many cases that were strictly orthopædic, and emphasized the importance of supplementing operative procedures with mechanical appliances. It was suggested that orthopædic surgery might be advanced if as much time was devoted to the clinical history and the pathology of the disease which produced deformity as to the devising of splints and modifications of splints. The importance of devising splints to suit individual cases and to meet certain conditions was regarded as an important part of orthopædic surgery. It was stated that the orthopædic surgeon seldom had an opportunity of putting a splint on a patient in the very first stage of the disease; that many of the cases of what was called early hip disease were not early cases, but that deformity had already arisen when they came to mechanical treatment. The same was true of Pott's disease of the spine. Some of the indications for operative interference were mentioned, such as the correction of deformity in these early hip cases by manual force under ether anæsthesia, by division of tendons and muscles, if the correction were difficult; and in the advanced cases, where the disease was fully arrested, osteotomy below the trochanter minor was suggested as a valuable addition to therapeutics. With regard to abscesses, incision was urged if four or five aspirations failed to relieve. It was further suggested that old sinuses and pockets of pus should be treated by operative interference. Operative interference in spinal disease was not recommended except where a severe trauma had fractured the lamina and where pressure had resulted. In these cases laminectomy was advised, but it was suggested that in many instances of this kind the ordinary mechanical treatment proved of valuable service. In disease of the knee partial arthroectomy was advised in preference to complete arthroectomy or to excision, especially in children. In the internal derangements of the knee operative interference was advised rather than the prolonged use of apparatus and fixation splints. In synovial disease, pure and simple, an occasional aspiration of the joint, with strapping, was regarded as good practice.

Dr. L. A. SAYRE said that the paper covered too broad a field to admit of discussing it in detail, but in general the author had expressed his own views most accurately.

Dr. RIDLON did not consider that the element of time was very important, except in those uncommon cases where it was the difference between a few weeks and several years. On the principle of leverage, he had been able to reduce the deformity in some of the very worst cases of hip-joint disease in a few hours or a few days as safely by mechanical means as by operation. It was only the question between a few days following an operation and a few days more with mechanical treatment, and under these circumstances we should not think of doing a cutting operation. In all cases of disease of the hip or of the knee leverage reduction would accomplish the result as well as an operation.

Dr. KETCH said that, while theoretically the orthopædic surgeon should be a good general operating surgeon, in practice he was not frequently called upon to perform operations, and hence could not be expected to be as skillful manually as surgeons who were constantly operating, and on this a natural division of labor was founded. He inferred from the paper that the author must have met with a class of cases in which it was unusually difficult to reduce the flexion, for, as a rule, there was no special difficulty about reducing this deformity, provided sufficient time was allowed. Forceful leverage or stretching added an unnecessary risk, as there was no way of accurately gauging the amount of force employed, and hence there was danger of inflicting traumatism which would result in lengthening the course of the disease and causing a speedy return of the deformity.

Dr. TOWNSEND thought there was one class of cases in which mistakes were likely to follow mechanical treatment, but which yielded brilliant results after operation—viz., the so-called peri-articular abscesses. Such an abscess situated outside of the hip joint often gave rise to symptoms simulating hip disease, and if it was not treated by operation there was great danger of its opening into the joint.

Dr. L. W. HUBBARD indorsed what Dr. Ketch had said about the treatment of deformity in the early stages; he had found that the reduction was usually quite rapid. He had never seen a case of hip disease in any stage, where there was motion, in which the deformity could not be reduced by position and traction in a short time, usually not over six or eight weeks. He could not see the force of the remarks just made about peri-articular abscesses, for they were just as likely to open externally as internally, and, as a rule, they healed quickly without operation.

Dr. H. W. BERG said that had it not been for careful attention to mechanical details such important orthopædic appliances as the plaster jacket, the long splint, and the Taylor brace would not have been known; yet orthopædic surgery should be broad enough to include within its scope both mechanical and operative treatment.

Dr. N. M. SHAFFER thought that many of the conditions described should necessarily come under the care of the general, and not the orthopædic, surgeon. We were all agreed, however, that the orthopædic surgeon should be competent to perform all the operations of general surgery, just as he should be able to diagnosticate typhoid fever, the exanthemata, etc. But it did not follow, because the orthopædist was prepared to perform these operations, or to diagnosticate the diseases coming under the care of the physician, that he should do either the one or the other, unless circumstances made it absolutely necessary. The speaker would have orthopædic surgeons devote themselves to the science and art of the mechanical treatment of deformities, using operative surgery as an adjunct to the mechanical work, rather than, as many were prone to do, make the me-

chanical part a sort of kite-tail to operative surgery. There was so much to be learned and so much to be developed in the continually broadening field of mechanical treatment that there seemed to be no excuse for the present tendency of orthopædic surgery to invade the well-recognized boundaries of general surgery. The tendency ought to be the other way, if orthopædic surgery was to succeed as a specialty.

Dr. R. H. SAYRE said that orthopædic surgeons should be competent to take charge of a case from the beginning to the end, whether it required mechanical or operative treatment. Limiting orthopædic surgery to the use of apparatus was like limiting the oculist to the application of glasses for the correction of refractive errors.

Dr. WHITMAN was unable to see the force or the application of Dr. Shaffer's remarks on the paper of the evening. A specialist was one by reason of the class of cases he treated, not because of the means he employed. The broadening field for this specialty was the study of the ætiology, development, and cure of deformities; the study of the course, complications, and ultimate results of joint diseases. Treatment must vary with the social environment of the patient and the severity and duration of the disease or deformity, and the most successful surgeon was the one who could best adapt the means to the end to be accomplished. Early diagnosis and efficient treatment would to a great extent obviate the necessity for operations, and it was proper for one who could select his cases to devote himself exclusively to mechanical treatment. On the other hand, many chronic and desperate cases of disease and deformity were brought to the institution with which he was connected. These patients would be neglected at home and rejected at general hospitals. Mechanical treatment alone in this class was ineffective, unless supplemented by an operation, which was often a necessary and a life-saving procedure. This exaltation of mechanics was opposed to the best interests of the patients, since, in the minds of many, mechanical and operative treatment, which were mutually dependent, were contrasted and opposed to one another; thus, on the one hand, patients were subjected to early and unnecessary operation and afterward neglected, and, on the other, the benefits of legitimate surgical interference were not appreciated. Why a broader and, as it seemed to him, more rational view of the subject need prevent the study and appreciation of mechanical supports was not apparent. Believing that disease was to be treated in its entirety, and not in phases, he was unable to accept the limitations that Dr. Shaffer would impose on the future development of orthopædic surgery.

The CHAIRMAN said that, if the orthopædic surgeon must be familiar with operative methods, as undoubtedly he must, he should also be a competent neurologist, for just as serious mistakes would follow ignorance of this subject as ignorance of operative surgery. Certain limitations were naturally placed upon one's practice, depending upon whether it was private or dispensary or hospital practice, for in the latter it was often not the best ultimate result, but the best that could be obtained within a limited time or with limited means, that must decide the plan of treatment to be adopted. The author's directions in regard to the reduction of the deformity in joint disease, and especially in certain stages of hip disease, while perhaps successful with him, would be exceedingly dangerous if followed by the general practitioner.

Dr. GIBNEY said that the great drawback to letting the general surgeon operate in orthopædic cases was that one frequently lost sight of the patients, and they were accordingly allowed to go without the use of protective apparatus and that careful treatment after operation which was necessary to insure a good result.

## NEW YORK SURGICAL SOCIETY.

*Meeting of December 23, 1891.*

The President, Dr. ARPAD G. GERSTER, in the Chair.

**Excision of the Hip for Disease.**—Dr. V. P. GIBNEY presented two cases. The first was that of a boy, four years and a half old, admitted into the hospital on June 30, 1888, with disease of a year's standing. At that time he was unable to walk, and stood with his weight on the left limb, with the right leg flexed at the hip and knee and adducted. There were two deep cicatrices on the posterior aspect of the hip, with two open sinuses having everted edges, and there was marked induration about the hip. The angle of greatest extension was  $135^\circ$ , that of greatest flexion  $120^\circ$ , and there was adduction over an arc of about  $24^\circ$ . The distance from the anterior superior spinous process of the ilium to the lower border of the inner malleolus was sixteen inches on the right side, seventeen inches and a quarter on the left side; the distance from the umbilicus to the lower border of the inner malleolus was sixteen inches on the right side and nineteen inches and three quarters on the left side. He had been operated on six months before in Worcester, Mass. His general health was poor. Excision was performed on July 17th, the femur being divided below the trochanter major. An effort was made to remove all the diseased bone within reach, and the acetabulum was thoroughly curetted. The limb was put up in plaster of Paris after a full antiseptic dressing. The highest temperature was  $102.4^\circ$  F. This was on the second day. It fell a point on the third day and after that did not rise above  $101.2^\circ$ . The splint was kept on for three months. On the 25th of August there remained a small sinus. On November 25th, the sinuses persisting, the patient was etherized and the tract of the sinus was curetted and injected with an ethereal solution of iodoform. By the 4th of January, 1889, the sinuses had closed. They opened again on the 8th and remained open until the 29th of May. On the 26th of January his limb could be extended to  $180^\circ$  and flexed to  $140^\circ$  without using force. Shortly after this he was attacked with measles and was sent to the Riverside Hospital, where he remained until the 22d of February, wearing his splint during the whole time. On the 13th of July the power of flexion was not quite so good, and that of extension was not equal to what it had been at the last measurement. The limb was parallel with its fellow and the cure seemed about complete. He spent the summer in the country, and in September the splint was removed. At the date of his discharge, October 10th, the angle of greatest extension was  $180^\circ$  and that of greatest flexion  $130^\circ$ ; adduction, abduction, and rotation were about half normal. The distance from the anterior superior spine of the ilium to the lower border of the inner malleolus was seventeen inches and a half on the right side and eighteen inches and three quarters on the left side; the distance from the umbilicus to the lower border of the inner malleolus was twenty inches and a half on the right side and twenty-one inches and a half on the left side. In other words, he had an inch and a quarter of real shortening and one inch of practical shortening. The thigh was three quarters of an inch shorter than its fellow, the knee half an inch, and the calf half an inch. The speaker had examined him again on December 19, 1891, and found his general condition excellent; he walked with a limp, but freely. The distance from the anterior spine of the ilium to the lower border of the inner malleolus was twenty inches and a half on the right side and twenty-two inches and a half on the left side; the distance from the umbilicus to the lower border of the inner malleolus was twenty-four inches and a half on the right side and twenty-five inches and a quarter on the left side; that is, there were two inches of

real shortening and three quarters of an inch of practical shortening. His thigh was an inch and a half smaller than its fellow, the knee three quarters of an inch, and the calf an inch. The angle of greatest extension was  $160^\circ$  and that of greatest flexion  $110^\circ$ . He had had no relapse since leaving the hospital.

The second case was that of a boy, four years and a half old, admitted into the hospital on February 13, 1890. His disease dated from June, 1888. In August, 1888, a splint had been applied in the out-patient department and had been worn since that date. A blow upon the hip in January, 1890, had done much injury, to all appearances, and he came into the hospital with the hip flexed at an angle of  $100^\circ$ , with great pain, and allowing of no motion. [A photograph was exhibited, showing his attitude at the time of admission.] The distance from the anterior superior spine of the ilium to the lower border of the inner malleolus was sixteen inches and a quarter on the right side and the same on the left side; the distance from the umbilicus to the lower border of the inner malleolus was seventeen inches and a quarter on the right side and seventeen inches on the left side; the right thigh was nine inches in circumference, the left thigh eight inches and a half; the right knee eight inches and three quarters, the left knee seven inches; the right calf six inches and three quarters, the left calf six inches. He was put to bed and a weight-and-pulley apparatus was applied with an inclined plane, but at the end of the month his condition was worse. The inflammation was very active, and on the 16th of May excision was done. Half an inch of the upper end of the femur was removed, along with what remained of its head, and the acetabulum was thoroughly curetted. Care was taken to remove with the scissors the soft tissues wherever they seemed to be affected. A counter-opening was made, a drainage-tube was inserted, and the hip was put up in full dressing with a plaster-of-Paris spica. On July 2d, less than two months after the operation, the operation wound had healed and a hip splint was applied. It was found that the knee was in marked recurvation, and a piece was attached to the splint whereby this could be corrected. The distance from the anterior superior spine of the ilium to the lower border of the inner malleolus was seventeen inches and a quarter on the right side and seventeen inches on the left side; the distance from the umbilicus to the lower border of the inner malleolus was nineteen inches and three quarters on each side; that is, there was three quarters of an inch of real shortening, but no practical shortening. The thigh, knee, and calf were each half an inch smaller than on the opposite side. He went to Saratoga for the summer and returned in the autumn, when the measurements were unaltered. On October 1st the angle of greatest extension was  $135^\circ$ , that of greatest flexion  $160^\circ$ . On November 5th a convalescence hip splint was applied. On February 25, 1891, the splint was removed and a shoe was employed with the sole a quarter of an inch thicker than that of the other shoe. On the 23d of March the boy had a fall, striking on his hip, and this caused some pain after a few days. On the 25th he was attacked with whooping-cough. In May, 1891, he had a sub-maxillary abscess, which was opened and soon healed. While he had the whooping-cough his splint was reapplied, and it was removed again in June. He seemed so weak in his hip that the convalescence splint was retained and he was discharged on the 9th of September. At that time the angle of greatest extension was  $150^\circ$ ; very little motion was presented; there was a little reflex spasm, also some tenderness. The distance from the anterior superior spine of the ilium to the lower border of the inner malleolus was eighteen inches and a quarter on the right side and seventeen inches and a half on the left side; the distance from the umbilicus to the lower border of the inner malleolus was twenty inches and a quarter on the right side and

nineteen inches and three quarters on the left side; that is, there was half an inch of both real and practical shortening. The thigh was three quarters of an inch smaller than its fellow, and the knee and calf each half an inch. He had been very active since leaving the hospital, and was examined again on the 19th of December. At that time the distance from the anterior superior spine of the ilium to the lower border of the inner malleolus was eighteen inches and a half on the right side and eighteen inches on the left side; the distance from the umbilicus to the lower border of the inner malleolus was twenty-one inches on the right side and twenty inches on the left side; the right thigh measured eleven inches and the left thigh eight inches and a quarter; that is, the left thigh had lost two inches and three quarters in circumference and the knee and calf each half an inch. The angle of greatest extension was  $155^{\circ}$  and that of greatest flexion  $140^{\circ}$ . There was some genu recurvatum.

**External Urethrotomy as a Preliminary to an Operation for Inguinal Hernia.**—The PRESIDENT presented a child on whom he had operated for the cure of double inguinal hernia after doing a preliminary external urethrotomy, which prevented contamination of the dressing by the urine. The urethral opening had proved a distinct advantage and the case was very satisfactory, as there was no sign on either side of a return of the hernia. Silver-wire sutures had been used to approximate the pillars of the ring. These had been removed from one side on account of suppuration due to an attack of scarlet fever; on the other side they had not produced any irritation.

Dr. F. LANGE recommended silkworm gut as a substitute for silver or copper wire for the closure of the ring. It was stronger, softer, and more elastic, consequently not so apt to cause mechanical irritation.

**Fæcal Fistula following Perityphlitis.**—Dr. CHARLES McBURNEY showed a patient on whom he had operated for the cure of a fæcal fistula resulting from a perityphlitic abscess. The operation had resulted in a complete cure.

**Perityphlitis.**—The PRESIDENT emphasized the necessity of early diagnoses and operations in perityphlitis. He observed fæcal fistula resulting from this affection only where the abscess was allowed to persist for a comparatively long time. The intestine forming part of the abscess wall was apt to slough if subjected to great tension by the abscess contents. Only recently he had observed a fatal and very extensive necrosis of the ascending colon, where a very large abscess was allowed to extend upward until the pus bathed the lower surface of the liver. Though the abscess was incised and drained on the tenth day after the inception of the trouble, the patient died with intensely septic symptoms, as the cause of which post-mortem examination revealed a slough of the colon three square inches in extent.

Dr. LANGE thought that the case narrated by the President had been one of those in which, on account of the anatomical position of the appendix, the abscess had developed behind the colon and had perforated into the retroperitoneal tissue. It was possible to approach these abscesses, even before their perforation, by a lumbar incision parallel to the crest of the ilium, which he had done in several cases. He had also operated in two cases in which, after infection of the retroperitoneal tissue, extensive sloughing had taken place. In one of these, for some time after the operation, fæcal extravasation of moderate amount had occurred, but the patient had eventually recovered. The other patient had been operated upon about four weeks ago and was now doing well and out of danger. In this case suppuration had extended as far up as the diaphragm. The speaker emphasized the advantage of proceeding against perityphlitic abscess, if possible, without opening into the free peritoneal cavity. He also mentioned one very severe case, still

under his care, which he had seen on the 25th of November, in consultation with Dr. Nicolai, thirty hours after the onset of the symptoms. This patient had septic peritonitis advancing so rapidly that in the course of an hour the physician had been able to observe a decided increase in the exudation. The pulse was 160, the temperature more than  $104^{\circ}$ , and the patient weak. Such patients were most apt to go into collapse after laparotomy and a radical operation. In this case he had perforated the rectovesical recess of the peritonæum through the anterior wall of the rectum, and had given vent to several ounces of stinking pus. The symptoms abated promptly and sufficiently to admit of laparotomy two days later, with removal of the appendix, which showed perforation near the point of its insertion into the colon. Fourteen days later a third operation was done for an encysted abscess below the lower border of the liver, and since then the patient had been without fever and was doing well. He had had fæcal discharges from the first abdominal wound for about a week, owing, probably, to the cutting through of the ligature of the appendix, which had had to be applied almost within the wall of the colon, on account of the perforation being so close to the latter. To the speaker this case had been very instructive in his effort to gain time, by a quick process which was not fraught with danger, for a radical interference, which the patient most probably would not have borne when suffering under the depressing effect of the acute process.

**Statistics of Operations upon Tuberculous Hip Joints.**—Dr. CHARLES T. POORE read a paper with this title (see page 449).

Dr. LANGE asked whether the author or any other member of the society had found symptoms which pointed to the localization of the osteitic process before perforation into the joint, so that one could say whether the femoral or the iliac constituent of the joint was affected. Dr. Poore had trephined the neck through the trochanter in a number of cases. What had led him to suppose that he would find the focus there? The speaker's own experience had convinced him that acetabular coxitis was observed almost as frequently as femoral, and he had tried to approach such foci in three cases without opening into the joint. In these cases tenderness on deep pressure and a slight tumefaction over the rim of the socket had been present, but the movements of the joint were comparatively free in spite of the fact that the disease was of considerable duration. In one case an intrapelvic abscess existed, which could be felt as a hard swelling through the rectum. This patient got well without removal of the head of the femur, though the joint was opened into during the operation and several years of mechanical treatment had to follow. The second patient had passed from his observation after having done well for a number of months. Later on he had seen the patient with all the symptoms of destructive joint disease and spontaneous dislocation of the head of the femur upon the ilium. He had not treated him since. The third patient he had operated upon at the German Hospital five or six years ago. In this instance the joint had to be opened to get at the focus, which was at the top of the socket. The femur was then replaced. He was unable to say what the final results in this case had been, but up to the date of the patient's discharge from the hospital he had done well. Theoretically, this method of procedure was rational, and it was a great functional advantage to the patient if the head of the femur could be preserved. His experience had been too limited to permit him to form a decided opinion.

Dr. POORE, in reply, stated that in his experience primary disease of the acetabulum was exceedingly rare, that he did not see how it could be detected, because the joint itself must become involved very early in the course of the disease, and the symptoms would be those of trouble within the articulation.

The vast majority of cases of tubercular disease of the hip began in the femoral portion of that articulation. The symptoms of articular osteitis were so well marked that he did not think the diagnosis was attended with any difficulty. He was satisfied that, if one intended to trephine, it should be done early, not after spasm had existed for a long time, for in the latter case the joint itself was probably involved.

## Miscellany.

**The Nature of Hysteria.**—The May number of the *Edinburgh Medical Journal* gives the substance of a communication to the Royal Medical Society by Lim Boon Keng, Queen's Scholar of the Straits' Government; Curator of the Library of the Royal Medical Society; Student of Medicine, Edinburgh University.

The subject, says Mr. Keng, is probably as old as medical literature itself. Yet the account given of it in our ordinary text-books is far from being satisfactory, in spite of the fact that most medical writers, from Hippocrates downward, have attempted to solve the problem. Indeed, a reference to the literature of this "neurosis" is not likely to give one much encouragement in the study of its nature. Instead of finding our difficulties solved, we are at a loss to know how to effect an escape from the tangled web of ancient, mediæval, and modern theories, whose number is legion! The doctrines of Hippocrates and his followers, founded on those of Pythagoras and Plato, are interesting enough; while the teaching of Galen, embodying as it does the essence of the humoral pathology of the older school, shows a decided advance, inasmuch as Galen and Aetius deny that the uterus moves from its place. According to Hirsch, in the Brahminical hymns hysteria is referred to as a disease of the nervous system. But in the Middle Ages science was in such a condition that demonology, which the Coan sage successfully discarded from medicine, again occupied the attention not only of the ignorant, but also of the learned. The credit belongs to the much-maligned Paracelsus for boldly asserting, amid much opposition, that the epidemic dancing manias were not due to the influence of evil spirits or such like. When the anatomy and physiology of the nervous system became better understood from the works of Willis, Sylvius, Descartes, Haller, and others, numerous authors began to regard the nervous system as the seat of hysteria. But from the time when the uterus was regarded as a roving animal, down to the eighteenth century, hysteria had been regarded as a malady peculiar to women. Sydenham was among the earliest observers to show that this neurosis was also seen in men, although he did not seem to make a distinction between hysteria and hypochondriasis. Without attempting to consider the views of Piso, Lepois, Stahl, Hoffmann, Cullen, Pinel, and a host of well-known writers, we pass to the most widely accepted theory in the present generation. Some thirty or forty years back, Romberg, Bright, Copland, and others associated the uterus with the nervous system in explaining the nature of hysteria; but no authority now maintains that uterine irritation or congestion is an essential element.

The favorite theory accepted nowadays is, of course, more scientific and rational than that of Piso or any of his contemporaries. It explains, however, as little as did "the animal spirits" of Sydenham and his school. The result is, therefore, no progress is made in the study of hysteria. In hospitals, cases of this affection are well recorded, but nothing is done in the way of research that is calculated to increase our knowledge of the pathology of hysteria. So long as no attempt is made to investigate this complex disease beyond staring, as it were, at our patients, no advancement need be expected. What line of research, then, is open to us? The answer will appear quite obvious when we have discussed the nature of hysteria in the light of modern physiology.

Hysteria is often described as a neurosis resulting from defective inhibitory power, or caused by a perverted will. The emotion and imagination have, as it were, rebelled against common sense and judg-

ment. But does this theory of "faulty inhibition" really inform us as much as to the nature of the malady; does it not rather tend to cover our ignorance? How often one hears "a general neurosis" or "functional disease" mentioned in reference to hysteria! These words mean nothing more than this—the disease exists, but we are ignorant of its nature. Unfortunately for some of us, these terms are sometimes employed as if they imply pathological entities. The perverted will, the exalted emotion, the erotic condition, the loss of controlling power, or the diminution of mental activity, can not, properly speaking, be the cause of hysteria any more than can we say that apoplexy is due to the loss of nerve power on one side of the body. The undue activity of the ideational centers and the diminution or perversion of volitional power are surely only the manifestations of the hysterical constitution. They presuppose a morbid condition which produces them rather than are in themselves causal factors in the production of hysteria.

The symptoms of mild cases of hysteria point to a morbid condition of the functions of the higher parts of the brain. They are capable of being explained by some *functional* disturbance, truly so called, of the cells concerned in ideation. The habit, education, and mode of life of the individual may be sufficient to produce this neurotic condition. It is more common in women than in men, simply because females are more easily excitable and more emotional than men. The perversion and exaltation of imagination may come on gradually or suddenly, according to the nature of the exciting cause. But the activity or sluggishness of the mental functions depends upon the same laws as those that regulate the functions of other tissues. The whole question, therefore, of the action of nerve cells—sensory, psychical, motor, or organic—is at bottom a chemical problem. The amount and character of the work done by the cells of the cerebral cortex determine, no doubt, the extent of waste products discharged into the circulating medium, and also the properties of these effete or transitional compounds. These cells must, like other cells, possess a maximum and minimum limit to their activity. Within this range their metabolism may be increased or diminished, and likewise the waste products of this intracellular change will vary, but they are not likely to produce obvious evil effects. They, no doubt, are largely concerned in causing the multitude of subjective phenomena complained of by hysterical patients. But it must be remembered that the perverted psychical functions are quite sufficient to give rise to nearly all the symptoms. Bad moral training, undesirable environment, sentimental reading, undue emotional or sexual excitement, especially if often repeated, aided by idleness or late hours, or both, may so disturb the psychical processes that the nervous system becomes exhausted. In this condition, those parts of it which have been little or not at all influenced by the will may be the first to indicate the *irritability* of the nervous system. But if the will, as is so often the case, has never been put to much use, then the weakness tells principally on the cells concerned in volition. In other words, this breakdown shows itself through the weak points. The inherited neuropathic diathesis is therefore an important element in the causation of hysteria. But even in one without a neurotic hereditary history constant undue attention to trifling sensations will and must, according to the law of summation of stimuli, produce in the end mischievous results by altering the modality of the normal processes in the nervous system. As surely as each additional link in a chain adds to its length, so does each response to central or peripheral stimulus augment the cell-activity occurring between the arrival of the afferent and the discharge of the efferent impulse. Thus ovarian irritation, fright, and so on, produce in such persons, neuropathic or otherwise, the characteristic features of hysteria. The constant association of this condition with movable kidney lends some countenance to our view. As an example of how a diminution of action in the nerve cells will explain certain cases of hysteria, it will suffice to point out the effects of the use or non-exercise of the will. Every one is aware of the difficulty of getting up early in the morning, especially if unaccustomed to do so. A person may lie wide awake—may feel he has something to do—but can not, rather will not, muster up enough courage to rise. The perversion of the will in certain cases of hysteria is an example of this condition in an exaggerated form. Under an unusual stimulus the greatest sluggard will be too glad to get out of his bed hours before the usual time. In like manner, by an unusually active stimulus we may bring these patients suffering from mild forms of hysteria to their common sense. No

doubt, as Dr. C. H. Jones remarked, a good whipping will sometimes do more good in these cases than all the antispasmodics, and will prove as efficacious as the much-vaunted hypnotic influence. In short, a moral treatment is what is required. This is much emphasized by Dr. Reynolds. In Dr. Wyllie's female wards in the Royal Infirmary a stomach siphon-tube hanging by the bedside sometimes acts as a charm in preventing vomiting which, perhaps, can not be easily controlled by sedative medicine.

But hysteria may show itself in much graver forms than we have hitherto considered. Besides subjective phenomena, it may produce symptoms that closely simulate those of organic disease. Sir J. Paget's chapter on Nervous Mimicry brings out this point very well. In these cases, which we must regard as the graver manifestations of hysteria, the *histokinesis* may be supposed to have passed beyond the usual range, or may have been otherwise perverted. In consequence, abnormal transitional products are thrown into the blood, and affect those parts most, or first, or solely, according to their affinities for them. In this way, probably, are produced the convulsions, paralysis, hallucinations, delusions, erotomania, visual aberrations, coma, and other phenomena, which are more or less permanent, until the patient has received proper treatment. In these cases, too, the purely nervous action is not ignored, but it is maintained that, apart from the perversion of nervous function, waste products, the result of this state of the nervous system, aggravate the condition. What the nature of these poisonous bodies may be is a subject for investigation. It is in the blood and body fluids that they must be looked for. Possibly they may be of the nature of albumoses or proteids of some kind. At any rate, the researches of Gautier justify our supposition, which is made only as a basis for purposes of investigation. In short, this assumption opens up a new line of research which, even if it does prove our supposition to be entirely fallacious, must tend to throw more light on the subject.

In conclusion, the nature of hysteria may be briefly said to be a psychico-chemical disturbance of the nervous system. The constant presence of nervous symptoms in chronic metallic poisoning, in malaria, lithemia (Murchison and Fagge), some forms of diabetes mellitus, and other diseases of allied nature, point to the importance of suspecting the presence of chemical bodies in the blood. Dr. Weir Mitchell's method of treatment is so valuable and efficacious because it insures the removal from the body of waste products whilst it tones up the nervous system. If this paper seems too wildly speculative to those who decry hypotheses based even on established facts, then the writer may ask what we know of the nature of diseases like diabetes, gout, rheumatism, and other forms of blood poisoning. Dr. Ferrier, on a recent occasion, referred to the value of speculations, and defined their proper sphere. In his great work he adopts a passage from Lewis as his motto—"Indeed every discovery is a verified hypothesis." The writer only hopes that this imperfect paper may lead some who have the opportunities to make a rational research into the nature of hysteria; so that in the treatment of this common malady it may not be said of us: "*Medicus nihil aliud est quam animi consolatio.*"

**The Song of the Bacilli of la Grippe.**—Dr. S. K. Davis, of Libertyville, Iowa, has sent us the following verses:

We're a band of jolly rovers;  
We have come, but not to stay.  
Though you think our visit lengthy,  
We will leave you by next May.

Like the icy winds of winter,  
You may feel us down your back;  
Or the raging heat of summer,  
When you think your head will crack.

But to see us, please remember,  
You had just as well be blind,  
For we're not on exhibition,  
We're not of the showy kind.

You may scan our field of labor,  
Bring the microscope to bear,  
But you'll only find the foot-prints  
That we left behind us there.

Scientists of every nation,  
Skilled in hunting down the germs,  
Have been thwarted in the efforts  
Made to bring us to their terms.

Doctors, too, of skill and knowledge,  
Have been seeking us to kill,  
But as yet they're undecided  
Just what thing will fill the bill.

Charlatans with vague conceptions  
How toward victims we behave,  
Have attributed our departure  
To the mixtures vile they gave.

But, intrenched in mucous membranes,  
At their efforts we grin in glee,  
Feast and fatten on quinine powders,  
And warm our feet in ginger tea.

Antifebrin, though so deadly  
To our friends the fever germs,  
Has no terrors for us fellows,  
For we're on the best of terms.

Phenacetin, though much lauded  
By the firms where it is made,  
Has been by progressive doctors  
Tried, and then laid in the shade.

In fact, we've waged bitter warfare  
With all drugs to science known,  
But have never yet retreated  
Till we made our victim groan.

Though to kill we've no ambition,  
Yet, to hear the stories told,  
You would think that all the graveyards  
Would not half our victims hold.

That many die is not denied;  
But here suspicion takes a breath  
And hints that drugs in heroic doses  
May, and do sometimes, cause death.

Antipyrine, though so potent  
To deplete the doctor's purse,  
Has outrivaled us in favor  
With the man that runs the hearse.

Old moss-backs of ancient laurels,  
Advocates of leech and lance,  
With "ten and ten" and antimony  
Seize the prize ere we've a chance.

If our victim treats us kindly,  
Stays indoors and keeps us warm,  
We will make our visit shorter,  
And will do him little harm.

But in cold and stormy weather,  
Should he take us out to freeze,  
He will soon regret the treatment,  
For we'll surely make him sneeze.

We will make his back and head ache,  
And his muscles pain him sore,  
And the tears run down his cheeks  
As they never did before.

We may shake him like an ague  
Till he's cold enough to freeze;  
Then we'll penetrate his lungs  
Till we make him cough and wheeze.

Or perchance attack the pleura  
Which all lungs are with supplied,  
And will penetrate this membrane  
To the cavity inside.

Sometimes we invade the sanctum  
 Of the thinking part of man,  
 And inflame the dura mater,  
 Though not usually our plan.  
 Instances, too, are recorded  
 Where our army did invade  
 The renal regions, and a siege  
 To Malpighi's tufts was laid.  
 In fact, there is no tissue  
 Of man's body, that we know,  
 But which we can, if needs be,  
 Take refuge in and grow.  
 But the membrane rich in mucus  
 Is the place that takes our eye:  
 There we grow and flourish best,  
 And our numbers multiply.

**Mortality in Cities in the United States.**—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for May 20th:

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—												
				Phthisis pulmonalis.	Yellow fever.	Small-pox.	Variceloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

**Results of the Application of Lannelongue's Sclerogenic Treatment in Tuberculous Affections.**—The *Lancet's* Paris correspondent says: At the French Surgical Congress M. Coudray furnished a highly interesting report on the results of the application of the new method of treating surgical tuberculous diseases devised by Professor Lannelongue. His report is founded upon sixty cases, including thirty-one of affections of the larger joints, nine of the lymphatic glands, six of the foot and fingers, and four of the spine. The results are stated to be excellent, recovery from the local lesion being the rule, and the propagation of the bacillus to distant parts being prevented through the formation of the sclerogenic barrier due to the chloride of zinc. What is the fate of the bacilli in their conflict with the new elements generated around the territory occupied by them? M. Coudray opines that they perish, or that, at any rate, their activity is paralyzed. This opinion is based upon three

microscopical examinations he has conducted on extirpated masses, and on the negative results of inoculations. M. Lannelongue explains the apparition of certain abscesses some time after the injection of the chloride-of-zinc solution by supposing that the bacillus colony is encapsuled temporarily. It is also possible that certain lesions may accidentally escape the action of the remedy. In a previous letter I wrote of the treatment of congenital dislocation of the hip joint by Lannelongue's method. M. Coudray tells us that a little girl of three years, thus treated five months ago, has now begun to walk, her lameness having diminished considerably. The femoral head now reaches during adductory and internal rotatory movements only to a point one centimetre above the line of Nélaton-Roser, instead of three centimetres, the point reached before treatment. M. Coudray has also essayed the method in the combating of such hopeless diseases as malignant tumors. Applied in three instances (two generalized malignant lymphadenomata and one cancer of the breast), the size of the growths seemed to be materially diminished and their development arrested. The difficulty is to circumscribe the infected lymphatic glands. MM. Ivesco, of Paris, and Dubois, of Cambrai, cited cases of surgical tuberculosis cured by them by means of the sclerogenic method, the practice of which will, doubtless, in time diffuse itself all over the civilized world.

**To Contributors and Correspondents.**—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

OBSERVATIONS ON  
THE EXCRETION OF URIC ACID  
IN HEALTH AND DISEASE.\*

By C. A. HERTER, M. D., AND E. E. SMITH, Ph. D.,†  
NEW YORK.

THE study of the end-products of nitrogenous metabolism, urea and uric acid, through which nitrogen is excreted from the body, has for a long time occupied the attention of investigators and to a less extent that of practicing physicians. The practitioner has concerned himself especially with the question of uric-acid excretion in its relation to disease, but the usefulness of his observations has usually been impaired, even for clinical purposes, by a very serious deficiency. This is that he has not had at his command any method of estimating, with even reasonable accuracy, the amount of uric acid in a specimen of urine. The presence of a considerable number of uric-acid crystals in the sediment of a urine has commonly been regarded as evidence of excessive uric-acid excretion. The important fact has been overlooked that the separation of uric-acid crystals or of urates depends more on the degree of concentration of the urine and its acidity than on the presence of uric acid in excess. In other words, such separation does not necessarily depend on an excess of uric acid. Nor, on the other hand, does the non-deposition of uric acid constitute evidence that a urine does not contain uric acid in excess. We do not wish to be understood that the separation of crystals of uric acid from the urine has no significance. Such a separation is more likely to occur when uric acid is in excess than when it is not, and when it occurs in the course of a few hours in a urine of which the specific gravity is less than 1.025 may perhaps be regarded as creating a presumption that there is an excess. The use, however, of such a criterion as this is responsible for many erroneous statements.

But supposing that the methods at the command of the physician could give him a reasonably accurate knowledge of the amount of uric acid present in a given urine, he would still be somewhat in the dark as to the significance of the result unless he was conversant with the variations in uric-acid excretion that occur in health. We propose in this paper to show what these variations are and upon what they depend, with a view to establishing a criterion for the use of those who wish to know the state of uric-acid excretion in special cases. We shall endeavor to point out especially the following facts:

First. That the absolute quantity of uric acid excreted varies chiefly with the character of the diet, being high on a highly nitrogenous diet and low on a diet of carbohydrates principally. In health the quantity of urea excreted depends on the quantity of nitrogenous food ingested.

\* Read before the New York Neurological Society, May 3, 1892.

† The determination of uric acid, and the chemical work generally, have been done by Mr. Smith at my request.—C. A. H.

Hence in health both urea and uric acid totals vary widely with the quality and quantity of the food.

Second. That the chief clinical criterion as to whether uric-acid excretion is normal, is not the absolute amount of uric acid excreted, but the ratio of the uric acid to the urea excreted.

Third. That the ratio of uric acid to urea in the twenty-four hours' urine from the same individual in health is fairly constant.

Fourth. That this ratio is not so constant for different individuals at different periods of life, but varies between 1 to 45 and 1 to 75.

We shall give the facts from which these conclusions have been reached. They are derived largely from original observation. In many respects our results merely confirm and extend those of other workers. We shall, however, call attention to certain facts regarding deviations from normal uric-acid excretion which, so far as we are aware, have been hitherto unnoted.

It is not easy to present the facts we wish to touch upon in simple and logical order. It is convenient to consider them under the following heads:

1. The Methods used in determining Uric Acid and Urea.
2. The Variations in Total Uric-acid Excretion under the Influence of Diet, Exercise, etc.
3. The Variations in Total Urea Excretion under the Influence of Diet, Exercise, etc.
4. The Quantitative Relation of Uric Acid and Urea in Health.
5. The Excretion of Uric Acid as influenced by Drugs.
6. The Excretion of Uric Acid in Disease.

1. THE METHODS USED IN DETERMINING URIC ACID AND UREA.

It is exceedingly important that we should mention briefly the methods employed in our work, since the character of the results and the reliance to be placed on them depends largely on correct methods. The error in much of the work that has been done on uric-acid excretion is due to the use of inaccurate methods of determining uric acid.

Of the numerous methods used in determining uric acid, that known as the Ludwig-Salkowski \* method is undoubt-

\* A good description of this method can be found in the last edition of Neubauer's and Vogel's work on the urine. The following modification of the method is employed by us: 200 c. c. of urine are treated with 20 c. c. each of the standard magnesian mixture and silver-nitrate solution, after the usual manner. With concentrated urine, of from 1.022 sp. gr. and upward, especially where highly colored, it is more satisfactory to take only 100 c. c., using 20 c. c. each of the standard solutions as before. After filtering and washing with ammoniacal water, the precipitate of phosphates and silver urate is removed from the filter paper into the beaker by the aid of a stream from the wash bottle, the paper being retained for subsequent filtration. Instead of using sodium sulphide for decomposing the silver urate, we employ a solution of potassium iodide, as suggested by Graves (*Jour. of Phys.*, 12, 1891). Occasionally, however, silver iodide appears in the filtrate, in which case it is necessary to redissolve the separated uric acid in weak sodium hydroxide and filter hot, when the urate is obtained in solution quite free from weighable traces of silver. For weighing, filter papers of 7 cm.

edly deserving of the greatest confidence and is the one employed by us. It is a gravimetric method of great accuracy.\* The drawbacks to it are the number of manipulations involved and the fact that it usually takes several days to get a result. It is not adapted for clinical work, and, unfortunately, there is as yet no method which is.

It is customary to calculate the urea of the urine from its total nitrogen content. This is accomplished either directly by the Kjeldahl process or the well-known hypobromide method, or, indirectly, by Liebig's urea method. The method used by us is Pflüger's modification of Liebig's method,† a volumetric process that has been well indorsed for clinical and research work. Among its advantages are its ready applicability and the relatively simple apparatus required. The method, however, only approximates a urea method, since other nitrogenous substances which are contained in the urine are estimated as urea. The chief of these are uric acid, creatin, creatinin, xanthin, and other extractives. These substances are contained in the urine in amounts that are small as compared with urea, but they make the results on urica determinations higher than they should be. We shall return to this point.

But while the Liebig method approximates a total nitrogen method, it differs from it in one important respect—namely, this: that it does not include the nitrogen of the ammonium salts. These are present normally in only small amount, but when administered for therapeutic purposes they appear in the urine in increased quantity, and hence increase the nitrogen as estimated from the total nitrogen present. On the other hand, the use of salicylates in large amounts leads to an overestimation of the urea as determined by the Liebig method, since the salicylic acid that appears in the urine is precipitated as urea.

## 2. THE VARIATIONS IN TOTAL URIC-ACID EXCRETION UNDER THE INFLUENCE OF DIET, EXERCISE, ETC.

Uric acid is the medium by which in man the largest amount of nitrogen, next that eliminated as urea, is excreted from the body. Recent investigations have made it probable that uric acid is formed chiefly in the liver and spleen; there appears to be no satisfactory evidence that it is formed in the kidney. The most interesting work that has been done on the source of uric-acid production is that of Schröder‡ and Minkowski.§ Schröder found that after the removal of the kidneys in birds uric acid continues to be formed and accumulates both in the blood and liver. He found, further, that the quantity of uric acid in the liver could be greatly increased after the removal of that organ from the body by passing blood through it.

diameter are employed, which are dried and weighed in small weighing bottles. The crystals are washed with about 30 c. c. of water and the usual correction for dissolved uric acid added to the weight actually found.—E. E. S.

\* Ludwig recovered about ninety-eight per cent. of uric acid from pure solutions. Two parallels on the same urine gave us 0.390 gramme and 0.382 gramme for the twenty-four hours.

† The chlorides are removed with a standard solution of silver nitrate.

‡ Ludwig's *Festschrift*, 1887, p. 89.

§ *Archiv f. experimentelle Pharmakologie und Pathologie*, xxi.

Minkowski's results confirmed those of Schröder. This observer removed the liver from geese and studied the effect of this removal upon the urine. He found that the urine, instead of containing sixty or seventy per cent. of uric acid, as it normally does, contained only two or three per cent. Coincident with this fall in uric acid there was a great increase in the amount of ammonia. Furthermore, the urine contained lactic acid. Minkowski thinks it probable from these facts that the liver is the chief agent in the formation of uric acid, and suggests that uric acid may be derived in the liver by the synthesis of lactic acid and ammonia.

The quantity of uric acid excreted daily by a normal adult varies considerably, and this variation depends more upon the character of the diet than upon any other factor. A highly nitrogenous diet increases the excretion of uric acid. A diet poor in nitrogen greatly diminishes it. A healthy man weighing one hundred and fifty pounds usually excretes between seven and ten grains (0.5 and 0.75 gramme) of uric acid daily. But it is a very important fact, and one which we wish to emphasize particularly, that the mere total quantity of uric acid in the twenty-four hours' urine gives no knowledge as to whether this quantity is or is not excessive. In order to obtain this knowledge it is essential that we should know what is the total quantity of urea (or the total nitrogen) excreted during the twenty-four hours in which the uric acid is estimated. We shall refer to this point again.

Exercise increases somewhat the quantity of uric acid excreted, but the influence even of vigorous and prolonged exercise is inconsiderable. The differences in uric-acid excretion at different ages are not exactly proportioned to the body weight of the individual. Thus, from the second year of life to the time of puberty the quantity of uric acid contained in the urine is distinctly greater in proportion to the body weight than in adults. This is due apparently to the greater relative assimilation of nitrogenous food at this period of life. It is said that during the first year of life the uric-acid excretion is more nearly proportioned to the body weight.

## 3. THE VARIATIONS IN THE TOTAL UREA EXCRETION AS INFLUENCED BY DIET, EXERCISE, ETC.

Urea is the chief end product of nitrogenous metabolism. Probably nearly ninety per cent.\* of the nitrogen that leaves the body is in the form of urea. Of course, the urea in the urine is not derived directly from the food taken into the body; it is necessary that the food should be first assimilated and its nitrogen become part of the tissues of the body before the ingested nitrogen enters into the formation of urea. Nevertheless, the quantity of urea excreted is, in a general way, proportioned to the amount of nitrogenous food assimilated. This is a most important fact, for it thus happens that the quantity of urea excreted is an index of the activity of the nitrogenous metabolism of the body. If an adult (of 150 pounds weight) is regularly ex-

\* Camerer gives this figure. See *Zeitschrift f. Biologie*, xxiv, p. 306. Other observers give somewhat lower figures.

erecting a large amount of urea daily,\* say 50 grammes or thereabouts, this is good evidence that there is extensive tissue waste, and if the individual is not losing weight we know that he must be assimilating a large amount of nitrogenous food. If, on the other hand, he is excreting a small amount of urea daily, say 12 or 15 grammes, it is safe to infer that a small amount of nitrogenous food is being assimilated, provided the weight is reasonably constant.

The influence of food on urea is well illustrated by the following observation: A man weighing 170 pounds, in good general health, and who was somewhat cautious about the use of nitrogenous food, passed in five consecutive days the following amounts of urea daily: 21.490, 22.591, 19.514, 19.649, and 19.989 grammes. He was then put upon a highly nitrogenous diet and the urea excretion jumped at once to the following figures: 28.701, 29.076, 19.799, 29.350, 37.268, 39.731, 41.203, 39.161, 38.126, 41.392, and 36.602 grammes. The subject returning to a less liberal nitrogenous diet, the urea fell at once to the following figures: 27.795, 29.191, 24.143, 23.034, 24.292, 26.549, 25.085, 23.150, 24.901, 22.362 grammes.

It is thus plain that the quantity of proteids ingested is the great factor in determining the amount of urea excreted. Other influences are of relatively little importance. Exercise, which was once thought to exert an important influence in increasing the urea elimination, has been shown to have little effect. The observations of Voit † on a dog made to turn a tread-mill, and those of Fick and Wislicenus ‡ in the ascent of the Faulhorn, are well known. More recently Parkes, § experimenting on soldiers, and North, || experimenting on himself, have shown that the increase of urea from exercise is exceedingly small as compared with the loss of body weight or the work done.

What has been said of the disproportionately large excretion of uric acid in childhood is true also of the excretion of urea. Thus reference to Table I will show that a child eighteen months old, and weighing twenty-eight pounds, excreted about 12 grammes of urea per day, while a child ten years old, and weighing one hundred pounds, excreted regularly between 25 and 30 grammes. This relatively greater excretion of urea in childhood than in adult life depends probably on the more active metabolism of child life.

We have already spoken of the importance of using the urea excretion as a standard in deciding whether the excretion of uric acid is normal or abnormal. We may now pass to a more minute examination of the quantitative relation

\* A normal man weighing 150 pounds and varying only slightly in weight excretes from 25 to 40 grammes of urea per day if he is on a mixed diet—i. e., his urea averages somewhere in the neighborhood of one ounce.

† *Untersuch. über der Einfluss des Kochsalzes, des Kaffees und der Muskelbewegungen auf der Stoffwechsel.* Munich, 1860.

‡ *Vierteljahresschrift d. naturf. Gesellsch. in Zürich*, 1865.

§ *Proceedings of the Royal Society*, xi, 339.

|| *Journal of Physiology*, i, 171.

of uric acid and urea in health, and subsequently to their relation under the influence of drugs and in disease.

#### 4. THE QUANTITATIVE RELATION OF URIC ACID AND UREA IN HEALTH.

We have stated that the quantity of uric acid excreted by a normal individual depends chiefly on the character of the diet, and we have stated that the quantity of urea excreted depends chiefly on the same factor. If we increase the assimilation of nitrogenous food beyond the average required, there is an increase both of uric acid and urea in the urine, and this increase in the two end-products is in a general way proportional. According to some observers, the uric-acid excretion increases a little more rapidly than the urea excretion. Other observers have found the urea output to increase a little faster, proportionally, than that of the uric acid, when nitrogenous food is increased. Our experience, so far as it goes, confirms the latter view, but it is possible that more extended observation would show that no general statement can be made as to this point.

The quantity of nitrogenous food assimilated by an individual in health who lives on a mixed diet and leads a reasonably regular life, of course varies a little from day to day, but not enough to cause a wide variation in the quantitative relation of uric acid and urea in the urine.\* We have analyzed the twenty-four-hour urines of a considerable number of persons, and have found the relation between uric acid and urea to be fairly constant from day to day, even though no effort was made to keep the quantity of nitrogenous food daily ingested even approximately the same. Reference to Table I will illustrate the truth of this statement.

But, while the relationship between uric acid and urea is thus fairly constant in the same individual, there is a much more considerable variation among different individuals of the same and different ages. It is difficult to give figures stating what is the average relation in health. We may say that in our experience the relation varies between 1 to 45 and 1 to 65 in adults. A relation higher than 1 to 45 we look upon with suspicion, unless it is known that it is a habitual relation, and that the individual is in good health. A relation lower than 1 to 70 is probably not met with in normal adults on a mixed diet. On a bread or milk diet, however, the relation may easily run as low as 1 to 80, or even lower, in health. Thus, Bunge † mentions the case of a young man whose urine showed a relation of 1 to 48 while he was on a meat diet, and a relation of 1 to 82 while he was on a diet of bread. In one case of *petit mal* the relation of uric acid and urea ran as follows on a mixed diet: 1 to 32.5, 1 to 36.8, 1 to 39.2, 1 to 43.2, 1 to 39.2. On an exclusively milk diet the relations ran as follows: 1 to 61.4, 1 to 66.1, 1 to 76.5, and 1 to 85.8. The absolute reduction in the excretion of uric acid was in this case even more striking than the relative reduction, for the total excretion of urea was distinctly reduced by the milk diet.

\* Of course, twenty-four-hour samples of urine must be used for comparison. It is also desirable that the patient should take little or no alcohol during the period of observation.

† *Lehrbuch d. physiolog. Chemie*, 1889.

It will be noted on examining the table that there is apparently little difference in the quantitative relation of the two end products at different times of life. Upon the whole it would appear that in children the average ratio is a little lower normally than in adults, but our observations are not sufficiently numerous to enable a definite conclusion to be drawn as to this point.

Newly born children are an exception to the general equality that holds for different periods of life.† It has been shown that during the first few days of life the relation of uric acid to total nitrogen excretion is much higher

than at any other period; but this exception is of no practical interest to us.

We have, then, in the quantitative relation between uric acid and urea a standard of practical utility by which it is possible to determine with confidence the state of uric-acid excretion. It is of course essential that twenty-four-hour samples be used, for the ratio between the two substances varies at different times of day, and a partial sample may not be a reliable index to the condition of the twenty-four hours' uric-acid excretion.\* Thus, a partial sample taken two or three hours after a meal rich in nitrogen might show a suspiciously high relation—say, 1 to 40—whereas the twenty-four hours' urine from the same individual might show a relation of 1 to 50, which would be, presumably, normal.

The variations that occur in health in the relation of uric acid and urea at different periods of the day have not been studied so carefully as could be wished. Camerer † has shown that, after a meal rich in nitrogen, the uric-acid excretion is at its highest during the hours immediately after the meal, while the excretion of urea is at its highest eight or nine hours after the meal. But Camerer's observations were made in cases where only one nitrogenous meal was taken in the twenty-four hours, and these cases did not conform in this and other respects with ordinary conditions.

It is necessary that we should say a word about the figures given in our table. As already stated, the Liebig method of determining urea is not, strictly speaking, a urea method; it is more nearly a total nitrogen method. Hence the ratios given in the table are lower than they would have been if obtained by the use of an ideal urea method. According to Camerer, ‡ about ninety per cent. of all the nitrogen the urine contains is present as urea; according to Bohland, § the amount is smaller, being about eighty-five per cent. of the total nitrogen. We might therefore have corrected our figures by the subtraction of ten or fifteen per cent. from the figures which we give for urea, but have preferred to give our first figures for what they are, and allow others to make a correction of this kind if they wish.

Haig || follows Garrod in giving 1 to 33 as the relation of uric acid to urea in health. There is thus a wide discrepancy between this ratio and the limits in health as given by us—namely, 1 to 45 to 1 to 65. This difference is not to be accounted for by the facts mentioned in regard to the urea method we have employed, since, even with the correction above suggested, there is still a wide difference between the figures. Moreover, the urea method used by Haig is open to precisely the same objection as that used by us. There can be little doubt that the reason for Haig's high figure is that the method used by him for determining uric acid (Haycraft's method) is faulty and regularly gives high results. This is conclusively shown by Herring-

\* *Zeitschrift f. Biologie*, 1889, 26 (p. 109).

ham and Groves\* in a recent paper. We have no hesitation in stating that a relation of 1 to 33 in a twenty-four-hour sample of urine is pathological. The ratios given by us for health correspond closely with the figures of Bunge, Vogel, Salkowski, and Pfeiffer.

5. THE EXCRETION OF URIC ACID AS INFLUENCED BY DRUGS.

From a practical point of view, no observations on the excretion of uric acid are of more interest than those which relate to the effect of drugs. Observations have been made upon the action of a variety of drugs, and in some instances conclusions have been reached that may be regarded as definitive; but much that has been written is of little or no value, owing to the inaccuracy of methods used in determining uric acid, or to more or less glaring defects in the conditions under which the experimental work has been done. In the case of some drugs there are conflicting opinions as to their influence upon the elimination of uric acid. We shall touch briefly upon the results of the work which, in our estimation, is most to be trusted. We may conveniently consider, first, the drugs that are supposed to increase the excretion of uric acid, and, secondly, those that are supposed to diminish it.

*Alcohol.*—As to the effect of moderate doses of alcohol upon uric-acid excretion the evidence is conflicting. According to von Jaksch, alcohol, in other forms than beer and wine, diminishes the excretion both of uric acid and urea. We have made some observations which bear on this question. A healthy young man, weighing one hundred and ninety pounds, was given whisky in increasing doses for three days. The first day the quantity taken was two ounces; the second day, three ounces and a half; the third day, six ounces. The urine was examined before and after the trial. The results are shown in the table:

TABLE II.  
*Showing Influence of Whisky upon Uric-acid Excretion.*

	Urea,	Uric acid,	Ratio of uric acid to urea.
First day before experiment, no alcohol.....	31.555 gm.	.599 "	1 : 52.6
Second day before experiment, no alcohol.....	37.401 gm.	.682 "	1 : 54.9
Third day before experiment, moderate use of beer and champagne.....	29.052 gm.	.601 "	1 : 48.3
First day on whisky, 2 oz. ....	36.425 gm.	.697 "	1 : 52.2
Second day on whisky, 3½ oz. ....	33.534 gm.	.620 "	1 : 54
Third day on whisky, 6 oz. ....	33.460 gm.	.630 "	1 : 53.1
First day after experiment, no alcohol.....	34.768 gm.	.657 "	1 : 52.9
Second day after experiment, no alcohol.....	32.768 gm.	.643 "	1 : 50.1

Inspection of this table makes it evident that in this case the whisky taken exerted no appreciable effect upon the excretion of uric acid. The relations between uric acid and urea on the days when whisky was taken co-

\* Herringham and Groves. *Journal of Physiology*, 12, 1891. These observers used the Ludwig-Salkowski method, but their normals give much wider variations than do ours.

incides with those of the days before and after, when no alcohol was taken. The slight change in ratio on the day before the use of whisky was begun may have been due to the use of beer and champagne on that day. With a view to seeing whether the influence of champagne (in quantities containing alcohol in amount approximately equivalent to that contained in the whisky) differed from that of whisky, another observation was made. The subject was given champagne in increasing amounts for three days. On the first day the quantity taken was eight ounces; on the second, sixteen ounces; on the third, twenty-four ounces. The results are shown in the table:

TABLE III.  
*Showing Influence of Champagne on Uric-acid Excretion.*

	Urea,	Uric acid,	Ratio of uric acid to urea.
First day, 8 oz. champagne.....	31.699 gm.	.754 "	1 : 42
Second day, 16 oz. champagne..	29.758 gm.	.655 "	1 : 45.1
Third day, 24 oz. champagne...	32.172 gm.	.686 "	1 : 46.8
Fourth day, no alcohol.....	32.947 gm.	.643 "	1 : 51.2

It is evident from these figures that while whisky had no effect upon the ratio of uric acid and urea, champagne in quantities containing an equivalent of alcohol caused a decided deviation from the habitual ratio owing to an increase in uric acid. It is interesting to note that the ratio returned at once to the habitual on the discontinuance of the wine. A single observation like this proves nothing, but is not without suggestiveness.

There is good reason to believe that doses of alcohol which in health cause no effect upon the excretion of uric acid, increase this considerably and disturb the normal relation to urea in persons with the uric-acid diathesis—*i. e.*, in persons who tend habitually to excrete uric acid in excess.

The best work that has been done upon the influence of large doses of alcohol is that of Chittenden and Smith,\* whose observations were on dogs in a state of nitrogenous equilibrium. There is no doubt as to the effect, at least in dogs, of the doses employed by these observers. While the total excretion of nitrogen was somewhat diminished, the elimination of uric acid was greatly increased, the increase amounting to about one hundred per cent.

*Sodium Salicylate.*—There has been some difference of opinion as to the effect of this drug, but recent observers

TABLE IV.  
*Showing Influence of Sodium Salicylate upon Uric Acid.*

	Urea,	Uric acid,	Ratio of uric acid to urea.
Day before salicylate.....	26.458 gm.	.478 "	1 : 55.3
First day on salicylate, 3 gm. taken.....	26.684 gm.	.555 "	1 : 48.1
Second day on salicylate, 3 gm. taken.....	31.420 gm.	.615 "	1 : 51.1
Third day on salicylate, 3 gm. taken.....	27.784 gm.	.730 "	1 : 38
Day after salicylate.....	27.805 gm.	.490 "	1 : 56

\* The Influence of Alcohol on Proteid Metabolism. *Journal of Physiology*, vol. xii, No. 3, 1891.

agree that salicylate of sodium causes a decided increase in uric-acid excretion as compared with urea. We have made the following observations on this drug: A young man in good health was given three grammes of sodium salicylate three times daily for three days. The urine was studied on these days, and on the day before and the day after. The results are given in Table IV.

In this case the effect of the salicylate of sodium was decided. The increase in uric acid was greatest on the third day of the trial, when the ratio to urea was 1 to 38. On the day after this the relation went back to 1 to 56—that is, to about where it was on the day before the salicylate of sodium was first taken.

Two similar observations were made upon persons who are subject to migraine. In the first case five grains of salicylate of sodium, t. i. d., were taken for three days. After this, ten grains, t. i. d., were taken for three days. The results were quite inconclusive. In the second case the quantity taken was three grammes daily for three days. The results in this case were also inconclusive. It is interesting that in both cases the use of the drug was accompanied by headache, which in the first case lasted several days and was general in distribution; and in the second case was a typical migraine paroxysm coming on at the end of the experiment.

*Alkalies.*—Alkaline waters are said by some to increase and by others to decrease the excretion of uric acid. Which of these views is correct we are unable to say. The question appears to call for reinvestigation.

*Quinine.*—In recent times the influence of quinine upon metabolism has been studied by Kerner,\* Prior,† and Sassetzky.‡ Kerner found that doses of 9·3 grains of quinine hydrochloride, continued for three days, reduced very considerably the excretion both of urea and uric acid. But while urea was decreased twelve per cent., uric acid was decreased fifty-four per cent. These small doses of quinine, therefore, greatly diminished uric-acid excretion, both absolutely and relatively. The experiments of Prior gave equally striking results as regards the diminution of uric-acid elimination, and Sassetzky, experimenting with fever patients, was able to confirm Kerner's observations.

Kerner's results have been criticised by Oppenheim,§ who found that a dose of 30·8 grains of quinine increased the elimination of urea by four grammes a day. Oppenheim believes that the results obtained by Kerner were due simply to interference with the proteolytic action of the gastric and pancreatic juices, which the use of quinine certainly causes. Prior has shown, however, that such interference does not satisfactorily account for the unquestionable retarding influence of quinine on proteid metabolism.

dine sulphate, found that small doses of the drug diminished the excretion of urea and that large doses (fifty grains) diminished both urea and uric-acid, the latter out of proportion to the former.

It is probably safe to conclude that the various salts of quinine in moderate doses diminish uric-acid excretion out of proportion to the urea excretion, but it is greatly to be desired that more extended observations on quinine should be made.

*Antipyrine.*—Only a few of the observations that have been made on the influence of antipyrine on nitrogenous metabolism include the study of uric acid, and these observations give contradictory results. Thus Umbach,\* experimenting both on himself and on a dog, found that four grammes of antipyrine in two days diminished slightly the excretion of total nitrogen, but had no perceptible effect on uric acid. Chittenden and Adams,† working on a healthy man, found that antipyrine in doses of thirty to sixty grains had a marked effect in checking the excretion of uric acid and urea, which were diminished nearly proportionately. More recent experiments by Kumajawa‡ are directly opposed in their results to those of Chittenden and Adams. This observer found that in a dog large doses of antipyrine (fifty-one grammes in sixteen days) produced no effect upon the excretion of urea, but increased the excretion of uric acid on the average to sixty-five per cent. above the normal. Obviously more work needs to be done before we can reach definitive conclusions regarding the effect of antipyrine upon uric-acid excretion.

*Antifebrine.*—The best work that has been done on the action of antifebrine on uric-acid excretion is that of Chittenden and Taylor.\* It was found by these observers that, in a healthy man, doses of antifebrine, varying from six to forty grains a day, slightly increased the excretion of urea, but decidedly diminished that of uric acid. The conditions of the experiments were such in this case that there is good reason to think that doses of more than fifteen grains daily of antifebrine have a specific effect in lessening the excretion of uric acid. This effect of the drug is of considerable interest in connection with the fact that in chorea and migraine, both of which conditions are associated with an excessive elimination of uric acid, antifebrine has been used successfully as a therapeutic agent.

Thallin,|| iron, lead, and mineral acids<sup>Δ</sup> are said to decrease uric-acid elimination; but the observations on which this opinion is based are not of a character sufficiently serious to require consideration here.

## 6. THE EXCRETION OF URIC ACID IN DISEASE.

We have seen that there is some lack of agreement on the part of writers regarding the influence of drugs upon uric-acid excretion. When we pass to the consideration of the relation of disease and uric-acid excretion we find an uncertainty about fundamental matters that opens our eyes anew to the imperfections of our knowledge.

Before referring to our own somewhat fragmentary work, which deals especially with nervous disease, we may advantageously review some of the more general aspects of the uric-acid question.

Not long since an English writer, Dr. Haig,\* attempted to show that uric acid is in some way the cause of a long and almost suspiciously varied list of diseases, including gout, rheumatism, migraine, epilepsy, mental depression, etc.

The idea of Dr. Haig is that these conditions are due, not to an increased formation of uric acid, but to its retention in the organism. Certain kinds of food, according to this view, render the blood less alkaline than normally, with the result that the uric acid formed is less perfectly dissolved than it should be, and is hence stored up in the tissues, instead of being removed from them.

This process of storing up continues until, as the result of an error or peculiarity in diet, the blood becomes more alkaline than before, and, in consequence of this increased alkalinity, the uric acid stored in the tissues is dissolved out into the blood. The blood (and consequently the urine) now contains a great excess of uric acid (uric acidæmia), and the patient suffers from uric-acid poisoning. This uric-acid poisoning is shown, in a general way, by a contraction of the peripheral arterioles, with increased blood-pressure and hard and slow pulse. The effects of the poison may, however, be shown in even a more striking way, as by an epileptic paroxysm, a migraine headache, or great mental depression, according to the particular predisposition of the patient. After a time the kidneys eliminate the excess of uric acid in the blood, and the blood ceases to acquire uric acid from the tissues, either because the tissues have no more uric acid to give up, or because the blood has grown less alkaline. When this elimination has occurred, the patient is once more relieved of his acute symptoms.

We believe this to be a fair general statement of the attitude of Dr. Haig regarding the relation of uric acid and disease. It will, however, repay us to examine his position somewhat critically.

Dr. Haig's views are based upon theoretical considerations and upon observation. Of the theoretical considerations on which these views rest, there are two which it is especially important to bear in mind. The first is that there is a varying condition of the uric-acid constituent of the blood, due to the varying alkalinity of the blood. The second is that the varying uric-acid excretion depends on corresponding variations in the storage of uric acid in the tissues, and not on changes in the formation of uric acid.

As to the first proposition, it may be said that, while it may safely be considered probable that the uric-acid con-

tent varies with the alkalinity of the blood, it must be admitted that there is no proof whatever that this is so. We know that uric acid is more soluble in highly than in weakly alkaline fluids, and there is nothing unreasonable in the supposition that a more alkaline blood would dissolve more uric acid, if it were accessible, than a less alkaline blood. But, if there is really a definite relation between the uric-acid content and the alkalinity of the blood, it is a fact susceptible of direct demonstration such as we might very properly demand. Yet, so far as we are aware, we have not even satisfactory evidence that the uric-acid content of the blood does actually vary in the same individual. Neither have we satisfactory information about the varying alkalinity of the blood in the same individual in health and disease. The point we wish to make is that the proposition of which we are speaking may be and probably is true, but that it is, after all, a mere supposition at present. We may use it, if we choose, as a working hypothesis, but we must not forget, as Dr. Haig appears to do, that it has not been shown to be a fact.

The second proposition—namely, that the variations in uric-acid excretion depend on the varying storage of uric acid in the tissues and not upon changes in uric-acid production—appears to be without any foundation and seems improbable. It is difficult, in the first place, to suppose that uric acid is produced in any definite quantitative relation to urea, as held by Dr. Haig. Both urea and uric acid result from cell activities, which must be undergoing such continual changes in intensity as to make it in the highest degree improbable that they are produced under all circumstances of health and disease in even approximately the same relation.

There is likewise no evidence whatever that uric acid is stored in the tissues and redissolved when the blood grows more alkaline. The formation of urate-of-sodium tophi in gout has been regarded as positive evidence that in gout, at least, there is such a storage. But the fact of the formation of tophi is susceptible of explanation in another and perhaps more satisfactory way. According to this view, the local mechanical deposition of sodium urate depends on local necrotic changes, which, in turn, depend on an excess of uric acid in the blood and not in the tissues.

We may now consider for a moment the character of Dr. Haig's observations on uric-acid excretion in disease. At the outset we are struck with the scantiness of the actual observations. On the urine of migraine a good many observations were made, but they were chiefly on one person and were made with an inaccurate method of estimating uric acid.\* The urine in epilepsy was examined, so far as we can find, in only two or three cases.† Yet Dr. Haig has no hesitation in elaborating a uric-acid theory of epilepsy on the strength of his facts. And so it is with mental depression, suicide, gout, uræmia, Raynaud's disease, and a long list of conditions which Dr. Haig refers to uric-acid poisoning. In each of these cases there is a huge superstructure of hypothesis upon a scarcely discernible basis of fact. We do not, however, wish to be understood

\* Hayeraft's method.

† *Uric Acid as a Factor in the Causation of Disease*, etc., 1892.

\* *Uric Acid as a Factor in the Causation of Disease*, 1892, Blakiston.

as contemning Dr. Haig's work absolutely. It is only just to say that his writings contain many interesting suggestions, and that his observations, though obtained by an untrustworthy method, are probably not without value. Indeed, we may say that Dr. Haig's work upon the fluctuations of uric-acid excretion in migraine is of much interest, notwithstanding its deficiencies, and contains the best observations that have been made on this aspect of the disease. What we especially condemn in Dr. Haig's writings are the sweeping conclusions that are drawn from so small a store of facts; we do not object to his ideas as suggestions, but we take exception to them as conclusions in fact.

It is instructive to examine briefly the state of knowledge regarding two conditions which are of wide general interest in connection with the uric-acid question—namely, uric-acid excretion in fever and in gout.

As regards uric acid in febrile conditions, it is generally assumed by authors that uric acid is excreted in excessive amount in fever from any cause, but especially in the case of fevers that are the result of conditions which produce embarrassed respiration (such as pneumonia, bronchitis, pleurisy with effusion, or pericarditis). There appears to be considerable doubt whether the uric-acid excretion is merely absolute or whether it is both absolute and relative as regards urea. Probably many of the statements that there is an increase of any kind in fever are based on the well-known separation of urates from fever urines. Scheube\* states that in the case of pneumonia he found both an absolute and relative increase in uric acid. On the other hand, Bartels† has shown that in many cases of acute febrile disease the uric acid excreted was present in normal proportion to the urea. It is thus plain that our knowledge regarding the influence of fever is in a most unsatisfactory state. It has been thought that the supposed increase of uric acid in fever urines was due to the defective oxidation of nitrogenous substances, but there is no support for this view. Thus Senator‡ and Nunyn and Riess# produced experimental dyspnoea in animals with a view to studying the effects of imperfect oxidation, but were unable to satisfy themselves that there was any alteration in uric-acid excretion. It has been often held that respiratory diseases in man cause increased uric-acid excretion, but there is no satisfactory evidence that this is so. The results that many writers have obtained are rendered worthless by the imperfections of their methods and their ignoring of the influence of diet. Bunge|| makes a very positive statement that in diseases of the respiratory organs the uric-acid excretion varies, in its relation to the excreted urea, within limits that are to be unhesitatingly considered normal. It is an interesting fact in this connection that in birds, whose respiration is the most active of any class of animals, nearly all the nitrogen excreted is in the form of uric acid. Indeed, nitrogen may be introduced into the body of a bird

in almost any form—as urea,\* as leucine, as glycocoll, as ammonium carbonate,† or as hypoxanthin‡—and the nitrogen reappears in the urine as uric acid and not as urea. It must be owned, however, that we should not allow these facts, whose significance is not clear, to weigh too much with us in the consideration of the relation between defective oxidation of nitrogenous tissues and excessive uric-acid excretion. We may, nevertheless, conclude that there is no good reason for referring excessive uric-acid excretion, in febrile or other conditions, to defective oxidation.

One might reasonably expect that in the case of gout there should be some well-established facts regarding the uric-acid excretion, since it is in this connection that most has been said and written about uric acid as a cause of disease. But when we come to examine the actual observations on the occurrence of uric acid in the urine in gout we find that most of them are of an unsatisfactory nature. According to Garrod, whose views have been widely accepted, there is an increase of uric acid in the blood during the paroxysmal period, due either to its over-production or defective elimination. For a long time this opinion was based entirely on the results of the well-known thread experiment, which is said by recent writers to be unreliable. Von Jaksch,# however, has recently shown, by actual analysis, that there is an excessive accumulation of uric acid in the blood in gout. Coincident with this increase in the blood there occurs, according to Garrod, a decided diminution in the excretion of uric acid by the urine. Recently Ebstein|| has attacked this view of Garrod and stated that it is in the highest degree improbable that there is any diminution in the uric acid excreted. He refers the results of Garrod to the use of imperfect methods. It certainly is difficult to believe that an excess of uric acid in the blood can be associated with a diminution of it in the urine. It is much more probable that whenever the blood contains an excess of uric acid there is a prompt increase in the elimination of uric acid by the kidney.

Probably the most satisfactory work that has been done in late years on uric acid in gout is that of Pfeiffer.<sup>Δ</sup> According to this observer, there is a decided diminution in the excretion of uric acid in all cases of gout, except during a paroxysm. This diminution he considers characteristic of gout, even in its earliest stages. When the cachexia of gout develops there is also a great diminution in the excretion of urea, and we are not clear whether or not, according to Pfeiffer, there is then merely an absolute diminution of uric acid or a relative diminution also.

During a paroxysm of gout there is regularly, according to Pfeiffer's view, an increase in uric-acid excretion, at least as compared with the excretion before and after the paroxysm. In some cases the diminution which regularly

<sup>Δ</sup> *Ibid.*

precedes the attack may persist during the first and second day of the attack, but in every case there is, contrary to Garrod's view, an increase during the paroxysm. Pfeiffer believes that in gout there is not necessarily any increased formation of uric acid, but rather a retention of it in the tissues and body fluids, owing to its being present in an insoluble form. We shall not, however, concern ourselves further with this question, which is largely one of theory. The observations of Pfeiffer appear to be well made, and his conclusions are consistent with what we know about uric-acid excretion. The one criticism it is necessary to offer on his work is that he employed a notoriously poor method of determining uric acid. We can not say to what extent this deficiency may have impaired the value of his results.

We have referred to the state of our knowledge as to uric-acid excretion in gout and in fever partly to illustrate the uncertainty that still exists regarding such common conditions. How little we actually have known until recently about uric-acid excretion in disease is shown by the remark of Bunge, in his recent work,\* that up to the present time (1889) there is only one disease in which it has been positively shown that there is an excessive excretion of uric acid—namely, leucæmia. But at the present time this statement would scarcely hold, for we have proof that there are several functional forms of nervous disease in which uric-acid excretion is abnormally large. We may pass to the consideration of these conditions.

Our own work refers especially to chorea, epilepsy, neurasthenia, and migraine, and we shall confine our attention especially to these forms of disease.

So far as we are aware, no observations have hitherto been made on uric acid in chorea, and our own work is not so extensive as could be desired. In four cases of chorea in which we have studied the urine there was a continuously excessive excretion of uric acid. This excess appeared to be proportional to the severity of the choreic movements, and grew less under the influence of treatment and in proportion as this was effective. We shall elsewhere give our data in full.

Not long since Haig advanced the proposition that epilepsy and certain kinds of headache, especially migraine, depend on temporary uric acidæmia. Haig's claim is that the epileptic paroxysm is preceded by a diminished excretion of uric acid, that the paroxysm itself coincides with an excessive excretion of uric acid, and that after the paroxysm the excretion falls quietly back to the normal.

This view appears to rest chiefly on the fact that in one case of epilepsy, recorded in the *Neurologisches Centralblatt* for 1888, Haig observed a diminution of the ratio to 1 to 50 (which he considers abnormal, 1 to 33 being his normal) before paroxysms, and of 1 to 20 immediately after them. Haig states that he has investigated other cases, but does not give figures that are satisfactory. He appears to recognize in some degree the insufficiency of the facts on which he bases his hypothesis, for he says that he would have liked to examine a large number of cases, but found the difficulties too great. Being, as he admits, unable to extend

his observations to his satisfaction, he abandons his investigations and retreats from fact to speculation. "I now look upon many other signs and symptoms," says he, "as more or less satisfactory evidence of uric-acid causation."

A similar indication of the insecurity of Dr. Haig's position is that he constantly attempts to support it by leaning on purely clinical considerations. He thinks, for example, that the uric-acid theory of epilepsy must be correct because there is a close clinical relationship between epilepsy and migraine, and he believes that he has shown migraine to be a "uric-acid headache."

We have made an extended series of observations on the state of uric-acid excretion in epilepsy. The detailed presentation of these observations and the conclusions that follow from them we propose to defer to another occasion. We may, however, say here that we have as yet obtained no grounds for the view that the *grand-mal* paroxysm of idiopathic epilepsy is regularly or even usually preceded by a diminished uric-acid excretion. On the other hand, our results support the view of Haig to the extent that we find the paroxysm to be usually succeeded by an increase in the uric acid of the urine. In many cases the increase is greatest on the second day after the seizure.

This latter fact suggests that the increase in uric acid is the result of conditions that are associated with, and perhaps determine, the paroxysm, and that this increase is not itself a cause.

We have made some observations which suggest that the uric-acid factor is of more significance in cases of *petit mal* than in cases of *grand mal* of idiopathic type. Thus, while the *grand-mal* cases in general have shown merely an increased excretion of uric acid after the paroxysm, the *petit-mal* cases have shown a large and persistent excess in the uric acid of the urine. That this excess has been in some degree related to the *petit-mal* seizures in three cases which we have examined repeatedly, was shown by the cessation or reduction in frequency of the seizures by the use of a diet which has lessened uric-acid elimination. This suggestion is further based on the repeated examination of the urine in seventeen cases of *grand mal*, many of which were placed at our disposal by the courtesy of Dr. Fisher. Up to the present time we have made one hundred and fifty-six determinations of uric acid in these cases of epilepsy.

Analysis of the urine from nine cases of pronounced neurasthenia showed in each instance but one an excess of uric acid. In this case the ratio was on the border line. In four of the cases the neurasthenic symptoms were referable directly to sexual excess. As a group these cases show nothing distinctive. A marked feature in some of the neurasthenic cases was a tendency to rather sudden variations in the ratio of uric acid and urea.

In all the cases that are tabulated below, organic disease of every kind was so far as possible excluded. The influence of alcohol was also barred out.

Our observations on migraine are few in number. In one case two paroxysms were studied; in another case only one paroxysm was studied. In each paroxysm a considerable excess in the excretion of uric acid was observed im-

\* *Lehrbuch*, 1889, p. 301.

mediately after the period of headache. No diminution of uric acid was found in the samples of urine passed immediately before the period of headache.

In two cases of paroxysmal vomiting in children we have made observations which we believe to be unique. Both the cases were under the care of Dr. L. E. Holt, from whom the histories were obtained. The first case is that of a boy, aged seven, who, since his third year, has had occasional periods of persistent vomiting, usually with headache and some rise in temperature. The paroxysms could not be referred to any intelligible cause. In the intervals the boy enjoys what is apparently perfect health. A twenty-four-hour sample of urine obtained in an interval of health showed a ratio of uric acid to urea of 1 to 56—i. e., a normal relation. A twenty-four-hour sample from the first day of a period of uncontrollable and repeated vomiting showed a ratio of uric acid to urea of 1 to 159. During the second day of the attack the relation was 1 to 134. On the third day the vomiting ceased and all the symptoms cleared up. The ratio on this day was 1 to 50, but it is certain that this relation is too low, as only the uric acid in the sediment was included in the analysis.

Fourteen weeks after this attack the patient had another. On the first day of the seizure the ratio was 1 to 164.8; on the second day it was 1 to 157. On the following day, as the symptoms wore away, the ratio was 1 to 24.9. We have in this case an example of an acute paroxysmal disorder, characterized especially by persistent vomiting, in which the attacks coincide in time with a very great diminution in the excretion of uric acid and are followed by a period in which its excretion is increased.

The second case which we have to relate belongs apparently to the same clinical type. In this case the patient, a healthy girl, aged four years and a half, developed symp-

toms which during two days justified a suspicion of tubercular meningitis. There were present the following conditions in the course of four days: persistent vomiting, obstinate constipation, marked retraction of the abdomen, irregular breathing and pulse, and, on the first and third days, slight fever. The urine of the first and fifth days was studied.

On the first day the ratio of uric acid to urea was 1 to 83.5—that is, distinctly low. On the fifth day it was 1 to 21—that is, very high. A normal specimen obtained some time later gave a ratio of 1 to 42.1. It is to be regretted that the examination did not extend over the entire time of the attack in this case, but the results, such as they are, are suggestive. A detailed presentation of these cases is given below:

Table illustrating the State of Uric-acid Excretion in Two Cases of Persistent Vomiting.

	CASE I.	Ratio of uric acid to urea.	
1st paroxysm.	Urine before paroxysm (normal).....	{ Urea, 13.606 grm. } { Uric acid, .2515 " }	1 : 54.2
	First day of paroxysm.....	{ Urea, 17.249 grm. } { Uric acid, .11 " }	1 : 156.9
		{ Urea, 12.023 grm. } { Uric acid, .0912 " }	1 : 131.8

	Second day of paroxysm....		
Directly following paroxysm			

	CASE II.	Ratio of uric acid to urea.
First day of paroxysm .....	{ Urea, 12.285 grm. } { Uric acid, .147 " }	1 : 83.5
Fifth day of paroxysm.....	{ Urea, 10.428 grm. } { Uric acid, .495 " }	1 : 21
After paroxysm (normal).....	{ Urea, } { Uric acid, }	1 : 42.1

We have touched upon some of the aspects of the uric-acid question which relate to clinical medicine. We have shown that in the investigation of a particular case it is necessary to study especially the quantitative relation that exists between urea and uric acid, for we can place little reliance on the totals themselves, which vary with conditions which we can not hope to control in clinical work. Since, as we have further shown, the variations in this relation are slight in the same individual in health, it follows that any considerable derangement of the normal relation is readily appreciable. The degree and persistency of any derangement in the relation may afford us a valuable index of the severity of condition with which we have to deal—a better index, perhaps, in some cases than the symptoms themselves, which may, as in the case of neurasthenia, be chiefly subjective. In many cases the variations in the quantitative relation, as the morbid condition progresses, may be advantageously noted with a view to watching the effects of treatment and of obtaining in this way facts for the establishment of a rational prognosis. We have ourselves been able to use some of our observations to advantage for this purpose.

But while we have thus dwelt upon some of the more practical relations of uric acid in health and disease, we have ignored the question which, of all the interrogatives of the uric-acid problem, is of the greatest interest. That question is, What is the significance of the excessive excretion of uric acid which is a concomitant of disease? Or, in other words, What is the relation of this uric acid excess to the cause of the morbid process? We doubt whether it is possible, at the present time, to give a satisfactory reply to this query, but shall endeavor to show, though it be but imperfectly, what are the considerations that should weigh most with us in trying to approach it.

The first fact to bear in mind in this connection is that excessive uric-acid excretion is a condition that is observed in a considerable number of clinical conditions. As we have already seen, it occurs in neurasthenic states, in migraine, in epilepsy, in chorea, in fever, in leukæmia, and as the result of the use of considerable quantities of alcohol. There can be no doubt that this excessive excretion is a common condition, and there is reason to think that a more extended study of the subject than has yet been made would show it to occur with greater frequency than has ever been suspected, especially as a consequence of disorders of digestion. Another fact of importance is that the conditions which have been enumerated as being associated with uric-acid excess differ widely in their clinical characters. It needs no argument to emphasize the clinical contrast between chorea and leukæmia, or that between an acute febrile and a neurasthenic state. But the fact that these conditions (so widely different that their comparison is amusing) have in common the excessive excretion of uric acid, leads us at once to the conclusion that this excess can not reasonably be regarded as the *specific* cause of any one of the numerous morbid states of which such excess is characteristic. It is certainly true that the conditions we have named differ as widely in their ætiology, so far as we understand it, as do the clinical types themselves. How, then, shall we interpret the important condition which these different types have in common? Our view of the matter is as follows:

Uric acid, like urea, is an end-product of nitrogenous metabolism. There seems to be no evidence to show that the formation of uric acid is a necessary precursor to the formation of urea. Such evidence as there is points to the idea that both these substances are the consequences of a more or less lengthy and varied series of metabolic changes, and that the formation of uric acid is expressive of merely a slight divergence from the process that ends with the production of urea.

An increase in the formation of uric acid, such as to make the quantity in the urine bear a higher ratio to the urea of the urine, is to be regarded as the result of a derangement in the development of the chain of nitrogen-holding substances that make their successive appearance for a short period of time between the commencement of digestion and the completion of destructive metabolism. What these substances are and how they are related to one another is still largely unknown to us, but there seems nothing unreasonable in the view that in conditions of dis-

ease the early links in the chain may differ from those that belong to health, and may possibly present a considerable divergence among themselves in different morbid processes.

But whatever may be the character of the original disturbance or of the morbid substances concerned in it, as destructive metabolism progresses there are only a few substances, so far as we know, through which these concomitants of deranged nitrogenous metabolism may be eliminated from the body. Of these, one of the most important appears to be uric acid.

According to this view, then, the increased excretion of uric acid that is met with in disease might be an *effect* of numerous different derangements in nitrogenous metabolism. We believe that this suggestion harmonizes with the fact that uric-acid increase may be brought about by so many different nutritional disorders. In this excessive excretion we should be dealing with the *result* and probably not with the *cause* of disease. Excessive uric-acid formation, in other words, is a terminal process that may result from different and perhaps numerous different initial morbid nutritive conditions. The fact that we can not now point out what these derangements consist in or with what poisonous substances they are identified, does not make less reasonable the view we have ventured to suggest.

#### A SIMPLE METHOD OF TREATING MANY CASES OF LACRYMAL OBSTRUCTION.

BY GEORGE M. GOULD, A. M., M. D.,  
OPHTHALMOLOGIST TO THE PHILADELPHIA HOSPITAL.

I ALWAYS suspect that system of therapeutics, whether political, social, or medical, to be wrong that proceeds on the assumption that its author could have given God some very good advice had the reformer been present at the creation of the world. In social science it is well recognized that any method of enduring progress must be based on helping Nature instead of disregarding or opposing her. In medicine and surgery the history of all failures is that "the fools rush in" with their little wisdom, supposed superior to the great wisdom of Nature, and, without study of the subtle ways and indications of the physiological processes, ruthlessly disturb or overturn the delicate measures of cure silently at work.

There seems to me a little illustration of this great truth in one small department of ophthalmic surgery—that relating to the condition of the lacrymal excretory apparatus giving evidence of itself by lacrymal retention, or even epiphora, lacrymal conjunctivitis, dacryocystitis, etc. There are, of course, a few cases in which the patency of the system is interrupted by closure of the intranasal orifice of the duct, the result of rhinitis, chronic or acute, malformation of the adjacent parts, indiscriminate use of the cautery, of the lacrymal probe, etc. There are others in which a genuine anatomical stricture may exist, the result of inflammation, morbid growth, traumatism with probes, etc. Without attempting an enumeration of such cases of lacrymal stenosis or occlusion, and admitting them out of this count, I wish to urge that the vast majority of cases

with symptoms of retention of tears are due to temporary and functional causes. There is a large number due to excess of secretion (instead of defective excretion) arising from eye-strain (overuse of a physiologically normal or an ametropically abnormal eye), from local irritations or congestions of many kinds, etc. There is another and still larger class of cases in which the abnormal conditions of the nares or nasopharynx by contiguity of tissue, or by duct-transfer of morbid material, living or chemical, to the upper part of the duct or sac, there set up congestion of the lining mucous membrane, and hence stenosis and retained secretions. It needs only the very slightest swelling of the membrane to narrow overmuch or to entirely close the patency of the tiny lumen of the canaliculus or duct.

Dr. S. D. Risley tells me that in examination of a number of dry skulls he found none the lacrymal ducts of which admitted the passage of the larger probes advised for "probing" the living, membrane-lined, and therefore narrowed, canal. This careful and excellent observer has long taught that the function of the duct is not that of a large drain, which it is not, but of a tiny capillary tube, which it is. The frequency of unhealthy nares, the abundance of dust and other pathogenic material, living or neutral, in our modern city life, that is sucked through the nares with every breath, or deposited in the conjunctiva between every wink of the eyes, furnish evident reasons for the overstimulation of the lacrymal or secretory apparatus, or for the functional interference of all grades with the act of excretion. A little narrowing, the irritation of a little retained morbid material, the extension up from the nose or down from the conjunctiva of a frequently-present local congestion or inflammation—and we have the eye bathed in tears, lacrymal conjunctivitis, or dacryocystitis.

Under such circumstances, what anatomic ignorance, what physiological stupidity, what therapeutic sin, to "slit up the canaliculus"—that wonderful little structure, with its sphincters about the puncta, and fashioned so patiently by Nature for a purpose and use—forever destroying its function, and, by brute force, jamming a rod of metal down among the congested membrane, wounding it in every part of its length by crushing it between the rigid probe and the bone, against which it lies in such close union! And yet this is the routine practice advised and carried out almost everywhere.

No wonder such cases are "obstinate." The cure creates the disease, and even worse; where before was only functional stenosis, there is doubtless often, by traumatism, organic stricture following inflammation set up by the probe injury.

Let us go at Nature less mechanically and brutally. Is there not a better way?

About a year ago I found blue pyoctanin (1 to 1,000) an excellent means of overcoming lacrymal conjunctivitis and disorders of the sac and duct, and I believe my colleague, Dr. De Schwcinitz, substantially agrees with me in conclusions from the experience. The effect is doubtless due to the powerful penetrating quality of the methyl violet, coupled with some antiseptic property. But it is almost impossible to use this drug without its highly objectionable staining

qualities becoming obtrusively manifest. I have therefore discontinued its use and have adopted another plan that seems to me based upon natural methods and to be an extension of Nature's indications.

Little children, in whom the fount of tears easily overflows, and in whom the excretory function is therefore put to most active use, are constantly "gouging" the "corners of their eyes," the inner canthi, with their little fists in a way that sometimes appears almost dangerous. Here, then, is the latest discovery in therapeutics—massage made use of by infantile wisdom. Even therapeutically, "babes and sucklings" may teach us if we are modest enough to learn.

In dacryocystic troubles every ophthalmic surgeon empties the sac by slow pressure upward and inward toward the inner canthus. How frequently in doing this we force a gush, seemingly absurdly great in quantity, of watery, mucoid, or purulent material, through the puncta—especially the upper one! But not following up the hint given by the babies, or by this latter procedure, the surgeon stops here and reaches for the knife and probes.

It would seem that the suggestion of massage, of continued and repeated emptying of the clogged sac by pressure, were worth trying. Perhaps massage alone would cure many cases. If now, without injury to the parts, we could refill these empty but congested canals with an antiseptic and astringent fluid, would we not at once and certainly cleanse, heal, and bring all back to physiological order? This is very easy.

First empty the sac and canaliculi by dexterous pressure, and cleanse the eye and palpebral pockets of this unhealthy material. Then cant the patient's head back and to one side, or have him lie so that a teaspoonful of liquid will be held in the depression formed by the nose, orbital border, and superior maxilla. Fill this space with a solution of boric acid,\* and with the little finger again slowly empty the sac and canaliculi by pressure, and then, as slowly lessening the pressure, allow these spaces to refill, by suction and capillary attraction, with the solution under which the puncta are submerged. Again, in half a minute empty the canaliculi and sac by pressure, but this time beginning the pressure from the canthus toward the nose and downward, so as to force the antiseptic solution downward into the duct. These alternate emptyings and refillings of the sac may be repeated several times and as often as desirable to meet the indications of the case. It will usually be found that the sac will soon become healthy and that pressure upon it will not cause regurgitation of morbid material through the puncta.

This treatment may not be "surgical," but it is "common sense."

A certain number of cases, however, will not yield to this treatment. There is too great stenosis or spasmodic contraction of the muscular sphincter of the punctum, etc., so that the cleansing solution can not be forced into the sac and duct. In such cases I am accustomed to insert one

\* The solution I use is composed, to the ounce of distilled water, of boric acid, ten grains; common salt, three grains; chloride of zinc, one grain—all deeply tinted with pyoctanin-blue, and doubly filtered after long standing.

sharp point of the iris scissors into the punctum and snip it open about one eighth of an inch, perpendicularly downward toward the conjunctival fold. This gives a larger opening for the indrawal of the solution.

I have been astonished to see how rapidly cases recover under this simple treatment that formerly would have seemed to demand slitting of the canaliculus and probing. I have been led to wonder if under the old treatment the good was not really done by the antiseptic or cleansing solutions commonly used with the surgical treatment—and, indeed, if the collyrium did not effect the cure in spite of the probing. I am thoroughly convinced that the very free use of antiseptic eye lotions, by the constant passage of the same through the duct, act therapeutically on nasal inflammations, that are themselves the primary causes or sources of conjunctival affections. Of course, a more effective treatment would be that of the nares direct.

One of the chief advantages of this simple procedure I would urge as consisting in the ability of the patient or of the patient's friends to carry on the treatment at home after a brief explanation and illustration by the physician. I am aware that some would consider this a disadvantage. Another and more important point in its favor is that general and family physicians can carry it out with the greatest ease. These, generally speaking, have not the necessary skill, or the special instruments for probing, etc., or they shrink from "interfering with the eye"; hence many patients, failing to seek the specialist's services, remain untreated and go on from bad to worse. A large proportion of such cases would find speedy relief by an application of the foregoing method.

## ETHER NARCOSIS

### AS INDUCED BY THE ORMSBY INHALER.\*

By J. A. WYETH, M. D.

IN the *Medical Record* for August 31, 1889, I saw the report of an address in surgery before the British Medical Association by Mr. T. Pridgin Teale. In this address he spoke in such terms of commendation of ether narcosis as induced by the method of Ormsby that I determined to satisfy myself of its value. For the last sixteen months I have employed it in private and public practice, and am convinced of its superiority to other methods of ether anæsthesia.

The apparatus consists of a rubber mouth and nose cover, a wire wicker sponge-holder, and over this a rubber balloon.

It is intended to furnish to the respiratory tract ether vapor mixed with and warmed by the expired air. It is claimed, and I hold justly so, that by warming this vapor some of the dangers of bringing a cold ether vapor in contact with the larynx, trachea, bronchi, and air-cells are lessened if not avoided. When it is remembered that the expired air has a temperature varying from 93° to 95.4° F., it will be readily understood how such heat will affect the vapor of ether with the Ormsby apparatus. The expired air is again inspired and breathed over and over again until there is added to the narcosis of ether a variable carbonic-

acid narcosis or asphyxia. In ordinary respiration only one fifth of the oxygen carried in by a single respiratory effort is absorbed by the blood. If there were no leakage to the apparatus, it is evident that it would take but a few respiratory efforts to consume all the oxygen caught in the mask and lungs, and that asphyxia must rapidly supervene. Such, however, is not the case in the practical working of the inhaler. I think that the partial asphyxia aids a rapid anæsthesia, dulling as it does sensibility and lessening the resistance to the absorption of the vapor. The degree of asphyxiation can be controlled and perfectly regulated by the trained etherizer.

In the list of cases to be given the condition of the urine before and after operation was carefully studied; noted the minute of commencing the administration; the time to complete insensibility and relaxation; time of operation; time of administration; time from removal of mask to restoration of consciousness; quantity of ether employed; whether or not vomiting occurred; and any notes of interest.

I wish to acknowledge the valuable aid so cheerfully given me in this work by the very efficient house staff at Mount Sinai Hospital—Dr. Leigh, Dr. Lovell, Dr. Sternberger, Dr. Cohen, Dr. Brodhead, Dr. Brickner, and Dr. Garrigues. I must also thank Messrs. Van Horn and Ellison, of Forty-first Street and Park Avenue, for the care they have taken to have the apparatus properly constructed.

Of forty-one cases, from the time of applying the mask to the time when the patient was relaxed and unconscious, the total was two hundred and thirty-eight minutes, or an average of five minutes and three quarters. From the time of unconsciousness until the ether was finally discontinued, eleven hundred and eighty-seven minutes elapsed; average, twenty-nine minutes. From discontinuance of the ether until consciousness supervened (reaction), two hundred and four minutes elapsed; average, five minutes. From commencement to completion of operation, eight hundred and eighty-six minutes; average, twenty-one minutes and a half. Quantity of ether poured out of ether bottle, one hundred and four ounces and a quarter; average, two ounces and a half.

In ten of forty-one cases vomiting ensued. In thirty-one of forty-one cases there was no vomiting.

The study of the changes in the urine gives the following result:

CASE I.—Carrie M., aged forty-five. Cancer of breast. Gland and axillary contents removed. Under anæsthesia fifty-five minutes; quantity, three ounces. Urine before operation, acid, sp. gr. 1.020, negative; after operation, acid, sp. gr. 1.030, trace of albumin; epithelium.

CASE VII.—S. S., aged ten, male. Plastic of leg. Under, thirty-five minutes; two ounces. Before operation, urine clear, acid, sp. gr. 1.020; oxalate of lime and granular matter. After operation, urine clear, acid, sp. gr. 1.032, trace of albumin, leucocytes, and oxalate of lime.

CASE XII.—A. B., aged twenty, female. Hæmorrhoids, clamp and cauterly. Under, thirteen minutes; one ounce. Before operation, clear, acid, sp. gr. 1.022, bladder epithelium, leucocytes. After operation, clear, acid, sp. gr. 1.010, trace of albumin, leucocytes, and epithelium.

CASE XIII.—M. S., aged forty-two, male. Hæmorrhoids, ligature. Under, thirty minutes. Before, cloudy, acid, sp. gr. 1.042, oxalate of lime. After, cloudy, oxalate of lime, hyaline casts.

CASE XVI.—J. S., aged thirty, male. Hæmorrhoids, ligature. Under, twenty-five minutes; three ounces. Before, cloudy, acid, sp. gr. 1.020, trace of albumin, granular casts, leucocytes. After, cloudy, acid, sp. gr. 1.028, trace of albumin, blood corpuscles, granular casts, renal epithelia, leucocytes.

CASE XXIV.—L. K., aged seventeen, female. Lupus of face. Under, twenty-one minutes; two ounces. Before, clear, acid, sp. gr. 1.025, epithelial cells. After, clear, sp. gr. 1.035, trace of albumin, hyaline and granular casts.

In ten cases albumin was present before operation and was not found afterward.

CASE XIX.—J. S., aged twenty-three, female. Cellulitis of hand. Under, seventeen minutes; one ounce. Before, clear, acid, sp. gr. 1.024, trace of albumin, blood cells, leucocytes. After, clear, acid, sp. gr. 1.030, negative.

CASE XXV.—L. R., aged twenty-seven, male. Peri-urethral abscess. Under, fourteen minutes; one ounce. Before, clear, acid, sp. gr. 1.025, trace of albumin, leucocytes. After, clear, acid, sp. gr. 1.030, no albumin, leucocytes.

In one case sugar was present, but was not affected by the anæsthesia.

CASE II.—S. H., aged sixty, male. Hæmorrhoids, ligature, clamp, and cautery. Under, thirty minutes; three ounces and a half. Before, clear, neutral, sp. gr. 1.040, large amount of sugar, no albumin. After, clear, acid, sp. gr. 1.042, large amount of sugar, no albumin.

Of the remaining cases, three were operated upon directly after admission, and no study of the urine was made before operation. Nothing abnormal was found afterward.

In six cases the urine was negative before operation and urates were found afterward. In one case clear before operation and cloudy after. In one case clear before operation and epithelium and granular matter after.

Directions for use :

1. Remove the sponge, cleanse in clean tepid water, disinfect in 1-to-500 bichloride solution; again wash it in clean tepid water, and squeeze thoroughly. The balloon and mouth-piece should be dipped in the bichloride solution, and immediately washed in tepid (not hot) water.

2. Pour into the sponge in position two ounces of ether. If the patient is nervous or unusually apprehensive of danger, for a minute or two gradually accustom him to the smell of the ether. Ask him to take a full inspiration, and, as the expiration begins, apply the mask tight over the mouth and nose. The sense of irritation and suffocation can thus be in the main avoided.

3. For the first minute or two allow no admixture of fresh air. At the first indication of asphyxia, the commencing purple in the ears or cheeks, tilt the mask a little to one side and allow fresh air to pass in. As it does not pass through the sponge, the ether vapor is not materially chilled. I usually tilt the mask at the commencement of one inspiration, and shut it down tight for this expiratory effort, and then hold it down for the next two or three respirations. From half an ounce to two ounces of ether may

be added, as the condition of the patient or the requirements of the operation may demand.

In conclusion, I am of the opinion that the proper administration of the anæsthetic, upon which so much of success and comfort depends, does not receive the attention its importance deserves from most surgeons and teachers. In our hospitals, as at Mt. Sinai, the internes should assist in the operating-room for six months before being intrusted with the administration of ether or chloroform. Every community of doctors should contain at least one man specially skilled as an anæsthetizer, as every surgeon of large practice keeps his trained assistant for this purpose.

Ether narcosis with the Ormsby inhaler, as above described, induces more rapid anæsthesia with a smaller quantity of ether, and permits a more rapid return of consciousness, than by the open inhalers which admit a free admixture of air. The danger of inducing laryngitis, tracheitis, bronchitis, and pneumonia is much diminished, and is practically avoided by the elevated temperature and the smaller volume of the vapor. The danger of disturbance of remoter organs, as the kidneys, is also diminished, since there is not the same saturation of the blood with ether, a smaller quantity being required.

Although this method is safer than the open-inhaler methods, we are still a long way from that surgical millennium of an anæsthetic absolutely free from danger to the patient or annoyance to the operator.

With ether and chloroform we must always be watchful. Both possess dangerous properties even in expert hands. Although I consider ether to be in general the safer agent, there are cases in which it is less safe than chloroform, and I consider it a scientific misfortune to have the dangers of chloroform or ether exaggerated *intra vel extra muros*.

## THE RELATIVE HUMIDITY OF THE ADIRONDACK REGION.

By WINSLOW W. SKINNER, M. D.,

MEMBER OF THE ANATOMICAL SOCIETY OF PARIS;  
FORMERLY RESIDENT PHYSICIAN TO THE ADIRONDACK COTTAGE SANITARIUM.

The climatic conditions obtaining in any popular health resort are objects of general interest. This is especially true if the resort be near great centers of population, if it be easy of access, and if it exercise special curative influence over a disease which attacks and destroys a large number of human beings. The "North Woods," or Adirondack region, fulfills these requirements, and among the several affections that are generally ameliorated or cured by a sufficient sojourning in this noted region, pulmonary tuberculosis is undoubtedly the most important. The great advantages derived by phthisical patients from an outdoor life in the Adirondacks are indeed evident and undisputed, and any statements made below should not in the least be regarded as detracting from the general favor with which this region is viewed by those who are aware of its healing virtues.

There prevails, however, in the profession and among the laity (although to a lesser degree in the former) an

erroneous idea concerning one essential factor in the climate of this region—namely, the relative humidity. Many persons well informed on most subjects have entertained the opinion that the atmosphere is much drier here than it really is, although this opinion is not based upon any exact data, but is a conclusion arrived at by analogy and deduction on naturally likening the Adirondaek resort to the earlier known Rocky Mountain resorts, where the relative humidity is comparatively low. It was thought that because the Western resorts for consumptives were dry, *all* good resorts for consumptives must also necessarily be dry.

The Adirondaek region, nevertheless, is damp; the mean relative humidity of the air there is comparatively high. This is shown by the carefully obtained figures given below, which result from daily observations taken by the writer during the past summer at one of the finest points of this region, the Saranac Inn. It is also shown by the reports of the observer\* of the signal station at the Hotel Ampersand, on the Lower Saranac Lake, as they were given to the writer by the chief of the Weather Bureau at Washington, Mr. Mark W. Harrington, to whom my thanks are due. Again, certain charts, based upon official statistics, represent the Adirondaek region as situated in the midst of one of the wettest territories on the continent. This territory embraces the northeastern part of New York and the adjoining parts of Vermont and of Canada, as well as the region of the great lakes. There are more cloudy days and greater rain-fall there than anywhere else in the eastern half of the country. Very fortunately, however, to offset this, the soil of the region is sandy and the surface is generally hilly or mountainous, so that the water precipitated from the clouds rapidly finds its way to the water-courses, or disappears from sight in the earth.

In regard to the relative humidity, the original data obtained by the writer give the following results: The total number of observations is eighty-seven. These were made three times daily during the month of August and a part of September, 1891, at the usual hours for such observations. From these eighty-seven observations, ranging from a relative humidity of 19 per cent. on August 19th to that of 94 per cent. on August 22d, it was found that the mean relative humidity was 70.5 per cent. The instrument used for taking these observations was given expressly for the purpose by the well-known firm of Meyrowitz Bros., Fourth Avenue and Twenty-third Street, New York. This instrument, the Naudet hygrometer, was compared with a standard wet-and-dry-bulb hygrometer until a proper coefficient of correction was obtained for every five degrees of its scale, thus affording approximate accuracy for every observation. It was further frequently compared with a Daniell's hygrometer, by means of which the dew point was obtainable at will in a few moments. This latter instrument was offered for this work by another large firm of dealers in scientific instruments, that of Eimer & Amend, of Third Avenue and Eighteenth Street.

The mean relative humidity of the Adirondaeks is greater in summer than in winter. According to the report

of the chief signal officer, the average for the period of four months, from June to September, inclusive, in 1889, at the Ampersand was 73 per cent., while that from December to March, inclusive, was 63 per cent. That of August, 1889, was 72.1 per cent., nearly two per cent. higher than that found by the writer during the same month two years later. The annual mean for 1889 was 68 per cent. It is thus seen that the figure 70.5, mentioned above, is in harmony with the observations of others. This mean, however, is lower than that of some other stations not far from the region in question. Thus the mean annual relative humidity observed at the station on Mt. Washington, computed from the commencement of observations to December, 1885, is 86 per cent., that of Oswego 78 per cent., and that of a New Jersey resort (Atlantic City) 80 per cent. All the stations in New England report a higher mean than that found in the Adirondaeks.

In conclusion, the following statements may be advanced:

1. Contrary to the generally received opinion, the Adirondaek region is comparatively humid, but less so than is New England.

2. Notwithstanding this, it is demonstrated to be an unusually excellent resort for consumptives when utilized in time.

3. Its excellency in this respect is due somewhat to its elevation and to its lower temperature, but chiefly to its rapid drainage, the purity of its atmosphere, the sparseness of its population, the presence of immense tracts of forest consisting largely of conifers (unfortunately, diminishing rapidly before the lumberman's axe), and to the great sense of mental repose impressed upon one who sojourns in this health-giving wilderness.

## NOTES ON SPASM OF THE ACCOMMODATION.

BY W. H. BATES, M. D.

CASE I.—A business man, aged thirty-six, several years ago complained that his vision for distant objects had failed. He could not recognize his friends across the street. Large signs could not be read until he was very near. He felt that he had become near-sighted. The cause of his poor vision he ascribed to continued writing by a poor light. After stopping the work which strained his eyes, he recovered without other treatment. Now his vision is perfect without glasses.

CASE II.—A lady, aged thirty-three, has had poor vision for a number of years. To obtain normal vision she requires — 1 D. S. After treatment of the eyelids for one week vision improved from  $\frac{3}{4}\%$  to almost normal,  $\frac{2}{3}\%$  —, without glasses.

CASE III.—An oculist, aged thirty, reports that ten years ago he was wearing — 1.5 D. S. to obtain good vision. Under atropine at this time he was still myopic. Several years ago, after an attack of measles, vision normal,  $\frac{2}{3}\%$ , without glasses. With the return of his general health the spasm came back and he was compelled to use — 1.5 D. S. to obtain vision of  $\frac{2}{3}\%$ . Atropine was used for several weeks until constitutional symptoms of atropine poisoning were produced. Vision under atropine  $\frac{2}{3}\%$ , with — 1.5 D. S. vision normal,  $\frac{2}{3}\%$ .

\* Mr. James P. Mills.

Later, without the use of atropine, he finds that there are times when his vision is normal,  $\frac{2}{30}$ , without glasses.

It is a curious fact that the spasm relaxed during ill health. The impression is prevalent among many authorities that ill health at least aggravates if it does not act as a factor in the cause of myopia. The following case also shows that the spasm may relax during ill health :

CASE IV.—A medical student, aged twenty-one, has been wearing four years a minus fourteen-inch glass with no discomfort, most of the time at a German gymnasium. The glasses were prescribed by a prominent oculist who used atropine for one week and made several tests. Lately, he being run down, his eyes have not been entirely comfortable. An examination without atropine showed a myopia of one half the degree of the glass he is wearing. Under atropine two days, patient is not myopic. I am indebted to Dr. H. Seabrook for the notes of this case.

CASE V.—An artist, aged eighteen, gave the history of myopia after an attack of measles when seven years old. Under atropine five days, vision  $\frac{1}{100}$ , w. — 1.5 D. S. =  $\frac{2}{30}$ . These glasses were prescribed for constant use. Several months later vision the same with and without the glasses as when under atropine. After remaining five minutes in a dark room with the eyes closed, rubbing the skin of the forehead a few times with the hand, and then testing the vision, it was found that the patient had temporary vision of  $\frac{2}{15}$  without glasses. The cause of the spasm in this case seemed to be due to the effect of light.

In the following case also there seemed to be spasm from the effect of light :

CASE VI.—A physician, aged thirty-five, has a vision of  $\frac{2}{30}$  in the right eye; the left eye has normal vision. After remaining in a dark room for a few moments, the vision of the right eye is normal,  $\frac{2}{30}$ , for a short time only. Under atropine one week, vision of the right eye  $\frac{2}{30}$ , with a minus twenty-inch glass, vision normal,  $\frac{2}{30}$ . After remaining in a dark room for a few moments and then testing the vision of the right eye in the light, vision is normal,  $\frac{2}{30}$ , for a short time only.

When treatment can relieve this sensitiveness of the eyes to the light, the spasm is sometimes relieved also, as in the following case :

CASE VII.—Mrs. H., aged twenty-three, is wearing —  $\frac{1}{6}$ . She has chronic conjunctivitis slight, with considerable pain in the eyes from the effect of light, especially gas-light. Treatment of the lids relieved the intolerance of light, and the vision became normal at the same time without glasses.

CASE VIII.—A stenographer, aged thirty, wore glasses to see at a distance.

April 29, 1888.—Vision of the right eye  $\frac{2}{70}$ , with —  $\frac{1}{20}$  vision normal. Vision of the left eye  $\frac{2}{30}$  +, and requires same glass to obtain normal vision. Cocaine applied to the mucous membrane of the left nostril improved the vision of the left eye. Cocaine in the right nostril did not improve the vision of the right eye to an appreciable degree. A number of operations were performed for the removal of nasal hypertrophies, etc.

May 15, 1888.—Vision of the right eye not improved. Vision of the left eye normal,  $\frac{2}{30}$ , without glasses.

June 1, 1891.—Three years later the left eye was still normal, the right eye still myopic.

CASE IX.—Mr. M., aged twenty, complains of being near-sighted. He has been tested three times under atropine.

April 5, 1888.—After using atropine for a week, pupils

widely dilated, throat dry, cheeks flushed. Vision of both eyes  $\frac{2}{30}$ , with — 2 D. S. vision normal. Ophthalmoscopic examination showed myopia. Cocaine was applied to the right inferior turbinate and septum of the nose, when the vision at once became nearly normal. At the end of fifteen minutes the vision returned to  $\frac{2}{30}$ , what it was before the application of the cocaine in the right nostril. The vision of the left eye was not materially changed by the application of the cocaine in the right nostril. A sharp projecting point on the right septum was removed with the saw after cocaine was applied. Vision of the right eye became normal,  $\frac{2}{30}$ , and remained normal.

July 15, 1888.—Three months later the vision of the right eye is still normal,  $\frac{2}{30}$ . The vision of the left eye is unchanged,  $\frac{2}{30}$ . Cocaine in the left nostril improves the vision of the left eye to the normal for a few minutes only.

CASE X.—A sailor, aged thirty-five, complained of recent failure of his vision. He required a minus twenty-inch glass to give him normal sight. Treatment for several weeks of the eyelids and nose with nitrate of silver and yellow oxide-of-mercury ointment improved the vision from  $\frac{2}{100}$  to the normal,  $\frac{2}{30}$ , without glasses.

CASE XI.—A colored girl, aged twelve, an epileptic, had always been near-sighted (?). Atropine was used in both eyes for a week. At this time, vision of both eyes  $\frac{2}{20}$  —; with a minus ten-inch glass the vision was normal. With the ophthalmoscope the fundus could be seen best with this glass, but there were moments when the light streak on the vessels could be seen with a far-sighted glass, convex twenty inches, but seen only dimly. The atropine was continued and the patient seen twice a week for five months, when the vision and refraction were found to be still unchanged. At the end of another month, altogether making six months' use of the atropine, patient had normal sight with a convex twenty-inch glass.

CASE XII.—A boy aged ten years applied for treatment.

July 12, 1888.—Until two years ago vision all right. He attends school in the winter months. Does not study at home. Under atropine two days, with the general symptoms of atropine poisoning, fever, dry throat, etc., vision in both eyes  $\frac{2}{30}$  +; with minus sixteen-inch glass, vision normal. He was kept under atropine ten weeks, with the result that the vision in both eyes became slowly normal without glasses. Atropine stopped. One month later vision still normal without glasses. Patient went back to school and resumed his studies. After a time the spasm returned; the use of atropine was followed by relief, only to have another relapse soon after returning to school. Patient was lost sight of for several years.

March 19, 1891.—Under atropine has a myopia of 3.5 D. S. Accommodation paralyzed completely by atropine. The atropine was stopped and a mild trachoma treated. The vision improved to  $\frac{2}{30}$  without glasses after a month's treatment of the lids, when the patient again disappeared.

It seems reasonable to infer that this patient might have been permanently benefited after receiving temporary relief if he could have been kept under observation and received proper care.

Conclusions.—1. Spasm of the accommodation can not always be relieved by atropine.

2. The vision of symptomatic myopia can often be improved so that glasses are unnecessary.

131 WEST FIFTY-SIXTH STREET.

Dr. Broadbent, of London, is announced to have been appointed physician in ordinary to the Prince of Wales, to succeed the late Sir William Gull.

## UNCONTROLLABLE VOMITING OF PREGNANCY.

By GEORGE N. MURPHEY, M. D.,  
BOWLING GREEN, KY.

THE pathology of this disease I shall not attempt to give, but only relate its clinical history and treatment. I have no notes of the case, and report from memory.

The patient, Mrs. O., white, twenty-three years old, married in October, 1891, had always been healthy, menstruated at thirteen, and was regular in her periods. On December 12th she was taken ill with vomiting due to pregnancy, which grew gradually worse until December 29th, when Dr. H. P. Cartwright was called and kept the case under observation until January 12th, when he asked me to see the patient with him. He had administered the following drugs without avail: Oxalate of cerium, creasote and hydrocyanic acid, bismuth, ingluvin, pepsin, cocaine, morphine and atropine hypodermically, mustard and fly blisters over the epigastrium, and hot douches to the cervix uteri. When I saw the patient she was much emaciated, as she had been able to retain food or drink for only a short time for four weeks; her temperature was normal; pulse, 120 a minute. We agreed that a little further trial be given some other drugs. I returned two days later with Dr. Cartwright, and found all drugs had failed us and that the patient was worse. The vomited matter now contained much blood. The patient was losing strength so fast that we ordered rectal alimentation to be given every four hours, day and night. The enemata, for the most part, contained the whites of two eggs, about twenty grains of table salt, and four ounces of warm water, occasionally alternating with milk, whisky, and water, which was continued for a period of two weeks. Twice during this time the bowel became intolerant of the enemata. The bowel was then thoroughly washed and given a rest of an hour. To the next enema twenty drops of the tincture of opium was added to sedate the bowel.

We now etherized the patient and dilated the cervix with the Wylie dilator; the os was exceedingly small, and the cervix of almost cartilaginous firmness. The uterus was found in normal position. We left and returned the following day, but the patient was no better.

We now concluded to bring on abortion, and for that purpose introduced a uterine sound to the fundus, placed a hard-rubber plug in the cervix, and tamponed the vagina with cotton for the purpose of preventing hæmorrhage, which the sound had caused, and to hold the plug *in situ*. This and subsequent operations were done under the strictest antiseptic precautions. At the end of thirty-six hours the patient had had no pains or symptoms of abortion, and vomiting was as severe as ever. We now introduced a large-sized soft-rubber catheter to the fundus with the intention of letting it remain for forty-eight hours if spontaneous abortion did not occur in the mean time. Everything went as usual for forty-two hours, when she was suddenly seized with a chill, and complained of being cold all over. I was present at the time, and found that she was almost pulseless and with a look that was death-like; in fact, the patient was collapsed. I immediately went to work to bring about reaction. I gave a full hypodermic of whisky, with ten minims of tincture of digitalis, also a rectal injection of three teaspoonfuls of whisky and twenty drops of tincture of opium in a teacupful of water as hot as could be borne. Hot bricks were placed to the feet, and hot wet cloths were placed over the stomach and abdomen.

Under such active stimulation the patient rallied in about twenty or thirty minutes, with a rise of temperature to 103.5°,

which I thought at the time was the beginning of septicæmia, but now entertain different notions about it for the following reasons: First, the temperature that had suddenly risen to 103.5° in eight hours thereafter had fallen to 102°, and in eight-een hours was again at the normal and remained so. Second, on removing tampons and the catheter, they were found free from foul and putrid odor. I sent for Dr. Cartwright as soon as the chill came on. He arrived an hour later; I had everything ready, and we proceeded to remove the contents of the uterus without further delay. The patient was placed across the bed in the Sims posture, a Sims speculum introduced, the posterior lip of the cervix seized with a volsella, and the uterus drawn low into the vagina. The dilator was again used and the cervix well dilated. The index finger was introduced, and the fœtus and its membranes were first removed, and then the placenta was carefully separated from its uterine attachment and removed in its entirety.

This operation was done without an anæsthetic, as we considered the patient too weak to take one with safety. It did not seem to cause her much pain, however, and there was but little subsequent hæmorrhage. Although much prostrated, under proper stimulation she reacted well, and had but few after-pains, the vomiting ceased, and she made a slow but good recovery.

## THE LOSS OF SMELL.

By GIBSLANI DURANT, M. D.

OF the senses, the least essential in man is that of smell, and it is for this reason that the many changes which may occur in this function are often unnoticed by both physician and patient.

While the loss of smell has not any profound effect upon the general health, yet it is an extremely disagreeable infirmity, both on account of the disturbance of taste which it occasions, and because of the uncertainty felt by the sufferer as to his personal surroundings.

*Anosmia*, the elasmia of Haly-Abbas and the Arabs—*olfactus amissio* of Sennert—may be congenital, and is then probably owing to absence of the olfactory nerve. Cases of congenital anosmia are not rare.

This condition may follow destruction or compression of the olfactory nerves or ganglia, by a tumor of the cerebral substance, meninges, or any one of the tissues at the base of the cranium, or may be symptomatic of a local or general affection. It accompanies inflammation of the pituitary membrane—at first from the dryness of the membrane at the beginning of the inflammation, and later from the quantity and character of the mucus secreted. The loss of smell may be occasioned by destruction or marked modification of the end organs, as in ozæna, syphilitic ulceration, or parasitic affections of the nasal mucous membrane. The nose in the above conditions is insensible to odors, as the tongue, when dry and parched or covered by a thick submucous crust, refuses to take cognizance of savors.

Sympathetic anosmia, more or less complete, is often seen in adynamic or typhoid fevers.

The only allusion to a relationship between arthritis and anosmia is made by C. Paul (*Bull. et mém. de la Soc. de théér.*, 1885). The subject was a lady, fifty-seven years of age—arthritic, undergoing change of life—with an entire absence

of the senses of smell and taste. Careful examination, says Paul, failed to show any organic lesion that might account for the absence of these senses.

It has often been said that gout is rare in women. In a certain degree this is true if the regular gout involving articulations is meant; but the gouty diathesis is as common in women as it is in men. It is possible, if we give it the requisite attention, to recognize the gouty nature of many cases of leucorrhœa and acute and chronic menorrhagia; the attacks coincide or alternate with fugitive pains in the fingers, heels, or great toes, and gout exists in the family.

In support of the theory of the possible relationship of gout and anosmia I relate the following case:

Early in October last I was consulted by Miss B. for a trouble more common than is generally supposed, but often neglected. The loss of smell and taste is complete. The taste is totally wanting, as much for bitters—colocynth—as for sweets or salts. The smell has also completely disappeared, for neither asafœtida, musk, nor ammonia is perceived by the patient. Placed near an open gas jet, she is not aware of it. As to flowers, they look beautiful, but have no odor.

The history of the case related by the lady is as follows:

She is twenty-seven years old; has had no sickness except rheumatism or neuralgia for three years. Her father and brother are both gouty. She has had the best of care at the hands of our most eminent medical men, but never received any benefit beyond partial relief from pain by morphine. Last May she was sent to Vichy, where for two months she underwent the routine treatment and took the regulation exercise, drank the waters, bathed, and was douched every day. She returned home late in August, somewhat improved as to her neuralgic (?) pains. Then she began to notice that she was gradually losing her sense of smell. For this she has been treated by nasal douches, sprays, fumigations, etc., all to no avail. The scraping of her nose having been suggested, she came to me.

On examining the external olfactory apparatus, no lesions were found, no trouble in the nervous centers, no chronic coryza. The mucous membranes, lingual as well as pituitary, have preserved their tactile sensibility. All other senses are normal.

As she still complained of pains in the joints, and also of late of an exaggeration of the sudoral secretion over the whole surface of the body (especially on the face), even though the weather was cold, arthritis seemed to me the only probable cause of the anosmia, and I determined to treat her for that alone for a while, selecting ichthyol as the remedy.

Under the administration of ichthyol in water twice a day, and the application of an ichthyol ointment, gently rubbed over all painful parts and covered by oakum and a bandage, I obtained in a few weeks a marked diminution of pain. I may say here that there never was any discomfort accompanying the internal administration of the drug; its only objectionable feature, that I can see, is the smell.

It is now four months since the patient came to me. To-day she is perfectly free from all neuralgic, rheumatic, or gouty manifestations. But of greater importance is the fact that the senses of smell and taste, which had been lost, have gradually returned, and are to-day as acute as they are in most people.

Bearing in mind that nothing was done to the olfactory organs, that they underwent no treatment whatsoever at my hands, are we not to believe that the anosmia was caused by the gouty diathesis?

12 WEST FORTY-SIXTH STREET.

## REPORT OF A DEATH FROM CHLOROFORM.

By J. C. REEVE, M. D.,  
DAYTON, OHIO.

THE following account of a death under anæsthetics, which took place recently in this city, is made up from the evidence taken by the coroner at an inquest held upon the case:

The patient was a male, aged thirty years. About two hours before the occurrence he was quite well, and at noon ate a hearty dinner. Dr. Kimmel was called to see him about three o'clock, found him suffering intense pain in the abdomen, and discovered that he had a hernia, and "also that his nervous system was very much shocked." He administered a hypodermic injection of a quarter of a grain of morphine, and left him to obtain assistance and get anæsthetics, as the man was suffering so much that a satisfactory examination could not be made. Dr. Shepherd administered the chloroform, which was Squibb's. The quantity administered is not accurately stated. "I had a four-ounce bottle not more than a quarter full, and we didn't use it all. We used a little ether, but it didn't amount to anything." Dr. Shepherd testifies that "we administered about three quarters of an ounce of chloroform, with a little ether added to it." It was administered on a cone of sponge without any covering over it. The patient seems to have taken it very well, with but little struggling. Dr. Kimmel testifies: "When I was examining the tumor I looked at his face and saw he was not breathing very well. I told the doctor to pull his head off the bed, and he did so. This seemed to be better for him and for me, for I reduced it very nicely and wasn't at it very long. He stopped breathing several times and revived again, and did that several times until it was all over." Dr. Shepherd testifies to the patient having stopped breathing several times and having revived again. Finally, immediately after the reduction, respiration suddenly ceased. Nothing is said of the pulse. Both physicians state that the heart was examined before the administration, and that its condition was satisfactory, but that the pulse was weak. Dr. Shepherd says the pulse was 48 and weak.

The means of resuscitation resorted to were artificial respiration (how long continued and the mode not stated) and "the injection of some whisky."

The coroner rendered a verdict that "deceased came to his death by nervous shock."

**The Medical School of Columbia College.**—We are informed that Dr. Charles McBurney has resigned his professorship of surgery in this institution (the College of Physicians and Surgeons), and been appointed professor of clinical surgery, and that Dr. Robert F. Weir has been appointed a professor of surgery to succeed Dr. McBurney.

**Surgeon Ainsworth, of the Army.**—Dr. Frederick C. Ainsworth, Surgeon and Major, has been nominated by the President for promotion to the rank of colonel and to be Chief of the Record and Pension Bureau at the War Department.

**The Natural History Society of Rhode Island.**—Dr. Horatio R. Storer has been elected president of the society.

THE  
NEW YORK MEDICAL JOURNAL,  
A Weekly Review of Medicine.

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 4, 1892.

THE PHARMACOLOGY OF ASPARAGUS.

ASPARAGUS is the edible lily. Belonging, as it does, to the same order of plants as the lily-of-the-valley, it is not wonderful that it has become a fascinating article of diet. Botanically, asparagus is nearly related to the asphodel, dear to the ancients, those two plants differing chiefly as regards their fruit. The old fables taught that the manes of the Greeks feed upon the roots of the asphodel, while the gastronomes of to-day delight in the tender shoots of this less comely liliaceous form. It is believed that asparagus was known to the Greeks, although probably not in the finely cultivated stage, in which it now comes to our tables. Pliny and other Latin worthies noted its peculiarities as an aliment, and the *Asparagus officinalis* is supposed to be the ἀσπάραγος of Dioscorides.

The plant is probably indigenous to England, and it was a favorite article of food there two hundred years before the art of its cultivation was brought over from Holland. The London markets dispose of vast quantities of this esculent annually, cultivated to a high point of perfection.

The root and shoots of asparagus are not yet discarded from the French *Codex*, as they have been from the *British Pharmacopœia*. The French use a syrup, to which are ascribed diuretic and soothing properties. At Aix les Bains and some other Continental health resorts this vegetable forms a notable part in the regimen of rheumatic patients. It does not agree with all persons alike; in some it occasions more or less gastric disturbance. Partly this may be due to the vegetable itself, since it is not always cut at the period of its tenderest growth, and partly an inadequate amount of cooking may give rise to indigestion.

An alkaloid was separated from asparagus as long ago as in 1805. This was named asparagine, and has been supposed to act, like convallaria and its preparations, as a cardiac sedative.

In former times the plant had some popular repute as an antilithic. The strong odor imparted to the urine of all who partake of the young shoots will account for this notion. Saccharinity of the urine has been observed after its use. It has been reported as the cause of urethritis and as an aggravator of that disease, but very little is known of the truth of these statements as a result of any systematic observations.

The pharmacology of this vegetable is worthy of a closer study than it has yet received. The profession has rested satisfied with the general feeling that the ingestion of asparagus was followed by a renal depuration, without entering a demand for proof thereof. According to the *Medical Press and Circular*, however, "there are grounds for believing that the asparagus tops not infrequently exercise a disturbing influence on the

renal functions, causing in some instances a notable decrease in the amount of urine excreted. It is very improbable, however, that any injurious effect is produced on the healthy organism, or this succulent vegetable would not have become a general favorite. As it may give rise to undesirable symptoms in certain special cases, it is well that the medical profession should be made acquainted with the real nature of its physiological action, and we shall look to our scientific pharmacologists for some information on this point." If this suggestion is carried out we trust that those who give their attention to the question will confine their researches at first to that part of the plant which is used so lavishly as an article of food. At the same time, it would be well to determine what differences, if any, can be found in the renal excretion, before and after the ingestion of asparagus.

MICROBIC MENINGITIS.

In the *Johns Hopkins Hospital Bulletin* for May, Dr. W. T. Howard, Jr., reports the case of an infant operated upon for imperforate anus in which the rectal wound suppurated. The child died in the second month, of purulent ependymitis, meningitis, and encephalitis, and a bacteriological examination of the pus from the inflammatory area showed the presence of a micrococcus and of the *Bacillus coli communis*. The child had atresia of the pulmonary orifice of the heart and patency of the foramen ovale and of the ductus arteriosus, and the reporter thought the feebleness of the circulation had favored the mixed infection by means of the suppurating rectal wound.

He calls attention to Netter's bacteriological examination of twenty-five cases of simple meningitis, in which the *Diplococcus pneumoniae* was found present in fifteen; the *Streptococcus pyogenes* in four; an intracellular diplococcus in two; a short, active bacillus, the bacillus of Friedländer, and a slender, small bacillus, respectively, in the three remaining cases. Monti also found the *Diplococcus pneumoniae* in the pus of four cases of meningitis; and the frequency of the presence of the pneumococcus is explained by the fact that meningitis is so often secondary to pneumonia and otitis media.

Besides these micro-organisms, Dr. H. M. Biggs reported, at a recent meeting of the Section in General Medicine of the New York Academy of Medicine, a case of meningitis in which he had found the bacillus of anthrax, although there had been no local focus of that disease on the body. It is interesting to note the varieties of micro-organisms that may cause meningitis.

MINOR PARAGRAPHS.

PHYSICIANS' FEES FOR PER DIEM SERVICES.

THE necessity that a prominent physician of this city has just experienced of suing a client for a bill for services entailing absence from the city must have been a very unpleasant ordeal. His services were requested by a business man of a Southern city, and his assistant, whom he sent in his place, was absent from the city for ten days. In the bill \$250 a day was charged for his services, and this the defense maintained was an

extortionate charge. Various prominent physicians of New York testified that they would have charged from \$300 to \$600 a day. Evidence was also presented that a physician could make a certain number of day and night visits that would remunerate him to the same amount as that charged for per diem services. But there is another feature of this subject that does not appear. This physician was called for his special knowledge and skill, and in all professions the individual has the privilege of disposing of his services for such remuneration as he sees fit. Not only this, but during an absence of one day even it would be possible for a physician to lose not only one but several cases that would remunerate him far more than the sum above mentioned, and it is for this reason particularly that it has been everywhere the custom to charge what might seem to be a high price for services entailing prolonged absence from one's place of business.

#### THE PRELIMINARY EDUCATIONAL QUALIFICATIONS OF ENGLISH MEDICAL STUDENTS.

THERE are many physicians who are rather fond of taking a pessimistic view of medical education in this country, especially in regard to the preliminary educational qualifications of medical students, and who express a longing for the more thorough general education that is required by the European medical schools. That the disparity is not so great as has been imagined is shown in an address by Dr. T. Clifford Allbutt, published in the *British Medical Journal* for May 14th. Dr. Allbutt says: "It is sad to hear it commonly said that the day of learned physicians is past, that they are gone with periwigs and *bric-à-brac*. And I have had already to observe, to my pain, that the Cambridge medical student of to-day is by no means 'learned'; that too often he thinks loosely, and that he does not always write even the English of the gentlemen who do the fires and the murders for the country journals. On his Latinity I will discreetly keep silence." Regarding the latter objection we must recall that the greatest English poet knew "small Latin and less Greek," and those geniuses who have made the greatest impression on the progress of medical science in this century have been men whose classical training was meager.

#### THE GOOD SAMARITAN DISPENSARY.

This institution is the successor of the Eastern Dispensary, one of the oldest and largest of the dispensaries of New York. As will be seen in our advertising columns, the trustees desire applications from candidates for appointment to the office of attending physician in the department of general medicine. We would direct our younger readers' attention to the advertisement, and add the remark that the Good Samaritan Dispensary seems to us, after careful inquiry into its methods, to have shown unusual care and wisdom in the selection and remuneration of its medical staff and in its attitude toward its beneficiaries.

#### COLOR-BLINDNESS IN THE NAVY.

A COURT of inquiry has made an instructive report regarding the causes of the grounding of the United States steamer Alliance in the harbor of Yokohama. It was proved that the color-blindness of a lieutenant who had entered the service as a cadet midshipman as far back as 1867 was the cause of the accident. In endeavoring to take the vessel out of the harbor this officer did not distinguish properly the danger-lights surrounding the breakwater. This mishap resulted in the discovery of the lieutenant's visual defect and will, it is said, lead to his retirement.

#### ITEMS, ETC.

**The Brooklyn Pathological Society.**—At the June meeting of this society, to be held on the 9th inst., the subject of the pathology of the respiratory system will be opened for discussion by a paper by Dr. J. M. Clayland. From the Hoagland Laboratory miscellaneous specimens will be presented by Dr. J. Van Cott, the president of the society.

**The Brooklyn Surgical Society.**—The special order for the meeting of Wednesday evening, the 2d inst., was a paper on The Surgical Treatment of Contractures, by Dr. A. T. Bristow.

**The Manhattan Eye and Ear Hospital.**—Dr. Thomas J. McCoy, of Los Angeles, has been appointed assistant house surgeon.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 22 to May 28, 1892:*

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon, will, upon the return of MUNDAY, BENJAMIN, Captain and Assistant Surgeon, to Fort Sully, South Dakota, proceed without delay to Fort Yellowstone, Wyoming, and report to the commanding officer for temporary duty with troops in the National Park during the season. Par. 1, S. O. 80, Headquarters Department of Dakota, St. Paul, Minn., May 24, 1892.

TURRILL, HENRY S., Captain and Assistant Surgeon, is granted leave of absence for three months.

DE LOFFRE, AUG. A., Captain and Assistant Surgeon. The leave of absence on surgeon's certificate of disability granted in S. O. 93, A. G. O., April 20th, is extended one month on surgeon's certificate of disability.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the week ending May 28, 1892:*

TURNER, T. J., Medical Director (retired). Granted one year's leave of absence, with permission to leave the United States.

HARRIS, H. N. T., Assistant Surgeon. Promoted to Passed Assistant Surgeon.

WILSON, GEORGE B., Assistant Surgeon. Promoted to Passed Assistant Surgeon.

GATES, MANLY F., Assistant Surgeon. Ordered to Naval Hospital, Portsmouth, N. H.

URIE, J. F., Passed Assistant Surgeon. Detached from Naval Hospital, Portsmouth, N. H., and ordered to the U. S. Steamer Chicago.

BYRNES, J. C., Assistant Surgeon. Detached from the U. S. Steamer Chicago, and granted three months' leave of absence.

#### Society Meetings for the Coming Week:

MONDAY, *June 6th:* German Medical Society of the City of New York; Morrisania, N. Y., Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Corning, N. Y., Academy of Medicine; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

TUESDAY, *June 7th:* American Medical Association (first day—Detroit); Massachusetts Medical Society (first day—Boston); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Columbia (semi-annual—Chatham), Franklin (semi-annual), Herkimer (annual—Herkimer), Niagara (annual—Lockport), Orange (annual—Goshen), Saratoga (annual), Schoharie (annual), Ulster (annual—Kingston), and Yates (annual), N. Y.; Hudson (Jersey City) and Warren (annual), N. J., County Medical Societies; Androscoggin, Me., County Medical Association (Lewiston); Baltimore Academy of Medicine.

WEDNESDAY, *June 8th:* Maine Medical Association (first day—Portland); South Dakota State Medical Society (first day—Salem); American Medical Association (second day); Massachusetts Medical Society (second day); New York Pathological Society; Metropolitan Medical Society (private); American Microscopical Society of the City of

New York; Medical Societies of the Counties of Albany, Cortland (annual), Dutchess (semi-annual—Poughkeepsie), and Montgomery (annual—Fonda), N. Y.; Philadelphia County Medical Society.

THURSDAY, *June 9th*: Maine Medical Association (second day); South Dakota State Medical Society (second day); American Medical Association (third day); Massachusetts Medical Society (third day); New York Academy of Medicine (Section in Pædiatrics); New York Laryngological Society; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga (annual), N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *June 10th*: Maine Medical Association (third day); South Dakota State Medical Society (third day); American Medical Association (fourth day); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties.

SATURDAY, *June 11th*: Obstetrical Society of Boston (private).

is undoubtedly as effective as iodoform. It is lighter in weight, does not cake, and is more readily dusted or insufflated. It is innocuous and free from disagreeable odor.

P. G. BECKER, M. D.

## Proceedings of Societies.

### NEW YORK NEUROLOGICAL SOCIETY.

*Meeting of April 5, 1892.*

The President, Dr. LANDON CARTER GRAY, in the Chair.

#### On the Present State of Treatment of Chronic Diseases of the Spinal Cord, especially of Tabes and Neurasthenia.

—Dr. LEONARD WEBER read a paper with this title. In deliberating upon the prognosis in any case of chronic disease of the cord, the first aim should be to distinguish between functional and organic disease. The first was dependent upon impalpable, the latter upon structural, changes. In a series of disorders, in spinal neurasthenia, in some cases of concussion of the spine, of hysterical paresis, and of toxic paralysis, palpable tissue-changes were generally not demonstrable. The molecular alterations were here presumably quite variable in a given series of cases, yet they might come to complete restoration, but they not infrequently persisted, particularly in neurasthenia gravis. In the treatment of chronic structural disease of the cord, tabes in particular, there were three methods of procedure which constituted our main reliance and which we put to use singly or in combination, according to the special indications of the case. As to the relation between syphilis and tabes and the amenability of the latter to treatment, the author was of the opinion that we were justified in using antisyphilitic remedies in a case of tabes with a syphilitic history, and, furthermore, that the results were better where the interval had been short between the infection and the appearance of spinal symptoms and where the case was not complicated by other disorders. The longer the lapse of time between syphilitic infection and the outbreak of spinal disease, the longer the duration and progress of the latter, the less was to be expected from a course of antisyphilitic treatment. In all cases of the kind it would be well to combine hydrotherapy and electrotherapy with the specific remedies. A combination of mercury and iodide of potassium seemed to offer the best results, inunctions of half a drachm of gray ointment and fifteen grains of the iodide two or three times daily. Authorities were not yet agreed upon the importance of the rôle which syphilis played in the ætiology of tabes, and we were not yet able to pass judgment on the therapeutic value of specific treatment of the disease, but we were also aware that some of the best men had reported favorable results and even a few cures. Symptomatic remedies were useful and often necessary to control pain. It was the author's practice to give antipyrine and acetanilide in combination. In regard to electrotherapy, no other remedy had been and was applied as much in chronic disease of the cord. From the crude way of its former use to the present rational modes of its application great progress had undoubtedly been made, but the reports as to the curative powers of electricity were contradictory, and it appeared to the speaker also that the number of observers who were losing faith in its value was increasing. Nevertheless, inasmuch as it could, when properly applied, relieve certain symptoms and by its stimulating and tonic effect benefit the patient, the author was not prepared to abandon its use. The constant current directly applied took precedence over all other methods. The faradaic brush was also

## Letters to the Editor.

### EUROPHEN IN MINOR SURGERY.

303 WEST NINETEENTH STREET, NEW YORK, *April 17, 1892.*

*To the Editor of the New York Medical Journal:*

SIR: The results obtained by me from the use of euophen have been most satisfactory and lead me to add my indorsement of its use as a substitute for iodoform.

In the case of a driver of a beer-wagon, the index and middle fingers of the right hand had been severely crushed by being caught between two barrels. There was a fracture of the middle phalanx of the index finger, with several deep lacerated wounds of both fingers. Several days before coming to me the patient had applied a carbolic-acid solution to the fingers, which had become of a greenish-black color. The fingers and hand were intensely swollen; there was pain in the elbow, and a dark, foul-smelling pus exuded from the wounds. The treatment was by thorough washing of the injured parts in bichloride solution, insufflation of euophen into the wounds, and envelopment of the fingers in a one-to-eight ointment of euophen and lanolin. Five days therefrom the swelling of the fingers had become reduced and there was less pus secretion from the wounds. The skin was still black and easily detached from the fingers in several places. A dark pus covered the denuded surfaces. As much of the cuticle as could be separated was removed, and euophen was dusted upon the denuded surfaces, as also into the wounds. This treatment was continued, and in about eighteen days the wounds were entirely closed, the cuticle having been freely and completely separated two days previously.

A child, four years old, was suffering from a large cervical abscess. It was opened and a large quantity of pus evacuated. The abscess cavity was curetted and euophen insufflated. The child was seen several days thereafter. Recovery was uninterrupted.

A child, aged three years, had had its buttocks and left lower extremity severely scalded by falling into a pot of boiling water. Carron oil was applied for forty-eight hours, followed by the dusting of euophen over the buttocks and half of the thigh. Boric acid and bismuth were used on the rest of the thigh and on the leg. As no deleterious results followed the application of euophen, its use was adopted upon the whole of the scalded surface. Recovery was complete with no untoward symptoms.

In several other minor cases I have used euophen, and in no case have poisonous results followed its application. Euophen

to be recommended. The third method of treating chronic spinal disease was by hydrotherapy. The sulphur bath was especially useful in spinal disease of syphilitic origin, in conjunction, of course, with antisyphilitic remedies. The author had no confidence in the heroic measures that had been recommended from time to time in the treatment of these disorders, such as revulsion, the cauterization of painful points, etc., as his efforts in these directions had not been attended with success. With the consideration of the treatment of spinal neurasthenia ("spinal irritation") the author closed his remarks. For the lighter forms, such as were observed in young people in consequence of sexual aberration to a moderate degree, or in the state of convalescence from various acute disorders, the removal of the cause, regulation of the mode of life, mild tonics combined with evening doses of bromides or other sedatives, the use of the steel sound where there was much urethral or prostatic irritation, a three or four weeks' course of mild galvanism to the spine, the cold sponge bath, and other suitable hydrostatic procedures, would generally be found sufficient to effect a cure. When it was practicable, a sojourn in the country and the use of cold baths of short duration was often advisable. Not so positive were the results of the treatment of neurasthenia gravis, as it might develop particularly in persons with a neurotic history after influences of an exhausting character, such as years of mental or physical overwork, sexual excesses, and prolonged and frequent masturbation at the age of puberty, when the entire central nervous system was often disturbed. It was true that the life of the individual was not put in great jeopardy by the vicious habit, but was often made very miserable, inasmuch as his capacity both for work and for reasonable enjoyment was very much diminished. Even in the neurasthenic the molecular changes in the nervous centers might be such that, on removing the cause and applying the proper treatment, functional readjustment might not be accomplished. Whatever progress had been made in the treatment of spinal diseases had not been due so much to the light furnished by the study of their ætiology as by clinical observation and practical personal experience.

Dr. W. J. MORRIS said he used mercurials in cases of locomotor ataxia, but did not regard the trifling improvement manifested as due to any antisyphilitic effect from the drug, but simply to its alterative properties, if he might use the ambiguous term. If syphilitic neoplasms were present, some good result might be expected from such treatment. He had been making observations upon patients as to the effect of electricity upon the excretion of urea and upon the temperature. The results had been surprising. Changes had always resulted. In some instances the temperature during an electrical *séance* had been from the normal to 100° F., and, when subnormal, had been raised a degree and a half.

The PRESIDENT had never seen the typical neurasthenic condition as a prodrome of organic spinal disease. He had, however, seen some forms of so-called sexual neurasthenia simulating disease of the cord quite closely. In some diseased conditions of the prostate or urethra or from mercurial poisons there might ensue a train of symptoms indicated by pain down the small of the back and along the sciatic, capricious and intermittent, and lasting for years, also an enormous increase of the cremasteric reflexes. There was an ataxia which seemingly resulted from syphilis. There was a cerebro-spinal form of syphilis in which symptoms of locomotor ataxia were present. It was a question whether true locomotor ataxia was not a neurosis. There were cases in which no lesion of the cord could be found. Some of these cases remained stationary for years after a course of treatment; or there might be some improvement and then general paresis. Again, the general paresis might improve. He had found that the great pain might often be re-

lieved by rest. The ataxia was a different thing to treat. Suspension gave marvelous results sometimes. He agreed that those who found no good in electricity as a therapeutic agent knew nothing about it. Galvanism in locomotor ataxia, especially in the neurotic forms, was of as distinct benefit as most drugs. Faradism of the motor-nerve troubles had also been of great benefit. We saw cases of neurasthenia gravis where there was a limited atrophy or disease of the ganglionic portions of the cord. Patients so affected were of feeble molecular power. Posterior sclerosis could arise which might have no connection with the condition, but he thought that every one who had observed many cases would find that in after years the elastic symptoms of tabes would develop.

*Meeting of May 3, 1892.*

The President, Dr. M. ALLEN STARR, in the Chair:

**Acquired Myotonia.**—Dr. GEORGE W. JACOBY presented a man with the typical phenomena of this disease. He gave a history of chancre a few years before, but of no further symptoms. He had first observed, nine weeks previous to his presentation, cramps in the hand, and found that flexion of the fingers caused tonic contraction. This condition existed to a marked extent in both hands, and some time elapsed before the hands could be voluntarily opened when flexed. The shoulders were beginning to be involved in the process. There were no sensory disturbances. Electrical examination gave myotonic contraction. Mechanical reaction over the hands, forearms, and shoulders was plainly demonstrated. The patient was a cigar-maker, and the speaker put the question as to whether the disease was a professional neurosis or not. It was not a case of Thomsen's disease, but the speaker thought that there might be a link between such cases, because he had seen a similar case of acquired myotonia develop into Thomsen's disease.

**Live Issues in Neurology.**—The PRESIDENT had selected this as the title of his inaugural address. After reviewing the work of the society for the past few years, he offered a suggestion in the mapping out of future work. It was that there should be a more general discussion of neurological subjects. Collective investigation of disease was certainly of the greatest value.

For such discussion, the subject presented many divisions, especially in cases in which the pathology was still an open question, also in the theory of disease. It should be sought to connect symptoms with underlying lesions. One of the interesting studies should be the possible relation of physiological chemical processes to the various functional nervous affections. Turning from theory to fact, would not some general discussion that would bring individual experience to a focus aid greatly in prognosis and therapeutics? It was only by co-operation that the society could be made of the greatest service.

The histories of three cases of angeioneurotic œdema were then read.

**Observations on the Excretion of Uric Acid.**—Dr. C. A. HERTER read a paper on this subject. (See page 617.)

Dr. L. C. GRAY said that the one fact of value elicited by Dr. Herter had been the relation of uric acid to disease, but he thought that one of the drawbacks to this knowledge being of practical utility was that we were not by any means positive as to the normal standard of the ratio. He could not say that he had observed the same action from a nitrogenous diet as the writer of the paper had. Dr. Herter had not classified neurasthenia, but the speaker thought that the ratio in the uric-acid excretion would be very different in cases of lithæmic neurasthenia.

Dr. B. SACHS thought that the paper could be used as a

guide by which to work up further facts in regard to this question of uric-acid excretion in health and in disease. He was satisfied that in treating a number of cases the uric acid had been reduced by a non-nitrogenous diet and plenty of fluids.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of January 27, 1892.*

The President, Dr. A. G. GERSTER, in the Chair.

**Deformity of the Thigh from Faulty Union of a Fractured Femur.**—Dr. PARKER SYMS showed a patient illustrating this condition, and asked for suggestions concerning the proper mode of treatment.

Dr. J. D. RUSHMORE suggested Macewen's operation.

Dr. F. LANGE suggested linear osteotomy, with a shoe with the sole an inch and a half in thickness.

Dr. SYMS agreed with Dr. Lange as to the use of the shoe, and had asked advice as to the feasibility of the operation, considering the danger from the stretching of nerves and vessels, which might be serious.

**Excision of the Elbow Joint.**—Dr. LANGE presented a patient, fifty-three years of age, on whom he had excised the right elbow joint for an old ankylosis with relapsing suppuration, the consequence of an osteomyelitis of the humerus, the primary attack of which seemed to have occurred at the age of eight years. At that time the elbow was not involved. Almost twenty-five years later the process must have recurred, with perforation, probably, into the joint. From the scar on the posterior aspect it was apparent that an operation of some extent had been done by the late Dr. Krackowizer. Healing had taken place with complete bony ankylosis at an angle of about 135°. About five months before, abscesses had formed again, after an interval of more than twenty years, and fistulæ remained which led to the bone just above the joint. The patient had suffered for several years past from a nervous trouble the symptoms of which pointed to a slowly progressing locomotor ataxia. In spite of that, the speaker thought excision of the joint and, through that, the removal of the diseased bone, was indicated. In the operation and after-treatment the plan was followed which he had explained in another case that had been presented at a previous meeting this winter, so-called chiseling excision, with preservation of a shell of bone corresponding to the important ligamentous and tendinous insertions. The after-treatment had been given by the apparatus previously demonstrated. Healing took place very rapidly, and, though the arm of the patient, on account of the ankylotic condition of the joint during more than twenty years, had become very atrophic, and his age and general condition excluded extensive new formation of bone, the joint was now—about two months after the operation—beginning to get somewhat useful. For a number of weeks the patient had not shown any ability to use the muscles which flexed or extended the elbow joint. Apparently he had entirely forgotten to use them co-ordinately. Every muscular effort was made from the shoulder or wrist joint, though, when the elbow joint was kept in a fixed position, not inconsiderable force could be executed by the extremity. The patient was soon able to elevate the arm, even in a flexed and pronated position of the forearm, but not until very recently had the use of the elbow itself been acquired. Perhaps, also, his nervous trouble had something to do with this inability to use his muscles with accuracy.

**Pes Valgus on Both Sides, operated upon after Trendelenburg's Method on One Side, and by Cuneiform Excision and Arthrodesis in the First Tarsal Joint on the Other.**—Dr. LANGE presented a patient, twenty-two years of age, from a healthy family and otherwise healthy, who had begun to suffer

in his eighteenth year. For about a year he had been treated with orthopædic shoes. During the past year his suffering had become quite intense, so that he was unable to stand for more than very short periods of time. Both his feet were extreme pedes valgi. The tendons of the extensors and peronei were contracted, and both active and passive motions of the feet were greatly limited and somewhat painful. The head of the os tali on each side protruded sideways and toward the ground, so that the inner border of the foot seemed to be elongated and the forefoot abducted. In the beginning of November Trendelenburg's supramalleolar osteotomy was done on the right side; but the resistance of the contracted tendons was so great that they, too, had to be cut across on the dorsum of the ankle joint and above the external malleolus. The remainder of the operation consisted in forcible correction and a plaster-of-Paris bandage. Three weeks later the left foot was operated upon. After a semilunar incision over the head of the astragalus the latter was partly chiseled away and a wedge of the joint elements was removed, the sharp edge being in the cuboid bone; and incision was then made over the outer half of Chopart's joint, and with a broad chisel the same was sufficiently freed to allow of an equal approximation of the os naviculare to the astragalus. The after-treatment was the same on both feet. Under the permanent antiseptic dressing and plaster of Paris, union took place without noteworthy suppuration. On the side where the astragalus had been excised the speaker had been struck by a softened condition of the bone and its greater volume, as if there had been a chronic inflammation with some osteoporosis. He had presented the case principally to allow of a comparison of the results in the two methods described. The patient was wearing flat-foot shoes with lateral splints to the knee joint, which kept the feet supinated, and it was intended that he should wear these protecting apparatuses for several months to come. The functional result was not yet perfect, owing to the short time that had elapsed since the last operation. The foot last operated upon was still weak and its motions were more limited than those of the other, the tendons of which had been cut across. With reference to the abnormal protrusion of the astragalus, the outlines were somewhat nearer the normal, but both feet might still be called moderate pedes valgi in spite of the not inconsiderable correction. For the present, on account of its greater mobility, the foot operated upon after Trendelenburg's method with tenotomies seemed to present a more promising outlook. It would be of interest to see the same patient about four months later, and it was his intention to present him again. He believed the operation indicated only in extreme cases where other remedies were of no avail. With reference to the methods to be chosen, a selection must be made which would be adapted to the requirements of the given case.

The PRESIDENT inquired whether, in the case of excision of the elbow, the open treatment and packing had been used.

Dr. LANGE replied in the negative. The available tissues were not abundant. The wound was allowed to fill with blood, and healed with the clot *in situ*.

Dr. F. KAMMERER observed that the patient seemed to him to have little power of motion in the flexor muscles, considering that several months had elapsed since the resection. He asked if it was advisable in such cases to try to get a movable joint, and if an ankylosis in a good position was not preferable.

Dr. LANGE replied that there was motion in certain directions. He supposed the muscle-consciousness, as it were, was still undeveloped.

Dr. WILLY MEYER, commenting upon Dr. Lange's second case, reported seven operations of supramalleolar osteotomy for ordinary flat-foot which he had performed upon four pa-

tients. In two of the cases, which were far advanced, walking was easier than before, but still slightly painful. Perhaps Ogston's operation should be added yet. In all of his cases he had found the bones abnormally soft. Trendelenburg had advised that the operation should be performed as near the foot joint as possible. The speaker believed that patients should be examined in a year or two after the performance of the operation. Only the permanency of the result obtained would prove the merits of the different operative methods.

#### **Sarcoma of the Femur, without Recurrence Five Years, after Amputation through the Trochanter Minor.**

—Dr. FRANK HARTLEY reported the case of a man, twenty years of age, who had been admitted into the Roosevelt Hospital, on October 9, 1886. The history showed disease in the knee joint for eight months. The diagnosis was that of sarcoma of the lower end of the femur, involving the knee joint. The patient was markedly anæmic. The thigh was amputated through the trochanter minor, and the patient was discharged, cured, November 29, 1886. There had been no recurrence of the disease. This fact was important because Borek, of Rostock, had collected a hundred and twenty cases of exarticulation at the hip joint for malignant growths, of which he found that in only eighty-seven had the patients recovered from the operation. Of the remaining patients, twenty-six had died from metastases—twenty in the first year, two in the second, one in the third, one in the fifth, and in two the time had not been determined. In six cases death had occurred in from twenty days to fourteen months after the operation, from disease unconnected with the original trouble. Four cases existed in which the patients had lived more than ten months, as follows: One lived twenty-seven months without metastases (Madelung); one lived two years and a half with metastases upon the back and beneath the arm, connected with the ribs (Czerny); one lived three years without metastases (Küster); and one lived thirteen years with a suspicious tumor in the arm. We did not cure these cases by disarticulation. Twenty-four of the twenty-six patients had had internal metastases, and two had had local recurrences.

The case now reported suggested the question of whether amputation at the trochanter minor, except in cases involving the bone near it, was not a less severe method of treatment than exarticulation, and one likely to be followed by equally good results.

Dr. J. A. WYETH believed that most of the patients upon whom amputation at the hip joint was performed for sarcoma of the femur perished within a year or less, from recurrence of the disease locally, or in the internal organs.

Dr. LANGE had operated in two cases of this character. One patient died from metastatic sarcoma of the brain; the other had been operated upon two years ago, and the speaker was not certain as to the result. Both had recovered from the operations without untoward symptoms.

The PRESIDENT had operated seven years ago at the trochanter minor, and there had been recurrence before the wound had healed. The patient left the hospital with an unfavorable prognosis. A very severe attack of erysipelas intervened, from which the patient recovered, and when he was seen, three years subsequently, the sinus of the original wound had healed, and there had been no recurrence of sarcoma.

#### **Ether Narcosis as induced by the Ormsby Inhaler.**—

Dr. J. A. WYETH read a paper with this title. (See page 629.)

Dr. RUSHMORE failed to see the advantages of the method over ordinary methods, judging from the statements that had been made. He did not feel sure that the expired air in the inhaler prevented the cooling of the ether vapor. If nausea and vomiting had occurred in twenty-five per cent. of the author's

cases, he believed the number was too great, and that carbonic-acid poisoning had had something to do with it.

Dr. F. GWYER had been impressed by the statement that ether should not be administered by inexperienced persons, as was the prevalent custom in hospitals.

Dr. LANGE remembered that the late Dr. H. B. Sands had recommended the Ormsby inhaler ten years ago. The speaker had used it six years, and had usually been satisfied with its action. The quantity of ether required when using it was small, and he agreed with the author in thinking that the number of those who were nauseated after its use was smaller than with other inhalers, though in his own experience larger than in Dr. Wyeth's.

Dr. C. K. BRIDGON thought that any form of apparatus by which the quantity of ether used was minimized would be desirable.

Dr. HARTLEY corroborated the statements made by the reader of the paper.

Dr. SYMS suggested a simpler and less expensive inhaler than the Ormsby, which included the advantages of the latter.

Dr. W. W. VAN ARSDALE feared carbonic-acid poisoning from the use of the Ormsby inhaler. A death from such a cause had recently occurred. Of course a single case was not sufficient to condemn the method.

The PRESIDENT showed a complicated apparatus for ether anæsthesia, invented by M. D. Hobbs, of Richmond, Indiana, which effected the warming of the ether vapor to body heat, and so diminished its refrigerating and irritating effect upon the respiratory tract. The apparatus was cumbersome, but in those cases in which it had been tried it had been demonstrated that it was not without merit.

Dr. WYETH disagreed with those who thought there was no advantage in anæsthetizing a patient rapidly. He believed that every minute saved to the patient from the influence of the anæsthetic was a decided gain. With other inhalers he had found that nausea followed an operation much more commonly than with the Ormsby. In patients who had been addicted to the use of alcohol he preferred chloroform as an anæsthetic. Rules were given for the proper care of the inhaler and for giving the anæsthetic.

---

## Book Notices.

*The Science and Art of Midwifery.* By WILLIAM THOMPSON LUSK, A. M., M. D., Professor of Obstetrics and the Diseases of Women and Children in the Bellevue Hospital Medical College, etc. New Edition, revised and enlarged, with Numerous Illustrations. New York: D. Appleton & Co., 1892. Pp. xviii-761.

This edition of Dr. Lusk's text-book is so thorough that, as the author says in the preface, it is "essentially a new book." However, since on its first appearance the work gave such a faithful representation of the best obstetrical teachings of the period, the author's task of revision must have been almost confined to the grateful work of recording the advance of his art. In other words, but few errors called for correction, and that fact must have left the author comparatively free to devote himself to the much pleasanter part of the work of revision.

Lusk's *Midwifery* is so widely known and so highly esteemed that a formal review of this fourth edition is uncalled for. The mere announcement that a revised edition has appeared ought to be enough to impress every general practitioner with the necessity of his possessing a copy of the book.

*The Pocket Pharmacy, with Therapeutic Index. A Résumé of the Clinical Applications of Remedies adapted to the Pocket-case, for the Treatment of Emergencies and Acute Diseases.* By JOHN AULDE, M. D., Member of the American Medical Association, of the Medical Society of the State of Pennsylvania, etc. New York: D. Appleton & Co., 1892. Pp. 204. [Price, \$2.]

THE author's pocket pharmacy consists of a pocket-case containing twenty-four varieties of tablet triturates that have been selected to meet the usual emergencies of daily practice; and any one objecting to one or more of the preparations could substitute others that he preferred. But with this particular selection the author describes under the name of each remedy the various morbid conditions in which it may be employed. There are mentioned many unfamiliar applications of old remedies, and we believe that their administration as indicated may prove valuable.

Small doses of each drug are recommended, and the most confirmed therapeutic pessimist can only say in the face of the optimism exhibited by the author that the amount administered can do no great damage even though all the good expected may not be accomplished.

The author believes that clinicians should study the effect of therapeutic agents upon diseased cells, and enriches our vocabulary by calling this "cellular therapy," considering that the light furnished by this doctrine will explain the therapeutic value of properly selected remedies.

We believe the work will be found interesting and useful to many besides the "intellectually rich though often technically poor" recent graduate.

#### BOOKS, ETC., RECEIVED.

*Atlas of Clinical Medicine.* By Byron Bramwell, M. D., F. R. C. P. Edin., F. R. S. Edin., Assistant Physician to the Edinburgh Royal Infirmary. Vol. I. Part IV. Edinburgh: T. & A. Constable, 1892. Pp. 141 to 184.

*The Diagnosis of Diseases of the Nervous System: A Manual for Students and Practitioners.* By Christian A. Herter, M. D., Physician to the Class of Nervous Diseases, Presbyterian Hospital Dispensary. New York and London: G. P. Putnam's Sons, 1892. Pp. viii to 628. Price, \$3.

*A Study of Influenza, and the Laws of England concerning Infectious Diseases.* A Paper read before the Society of Medical Officers of Health, January 18, 1892. By Richard Sisley, M. D. Lond., M. R. C. P. Lond. etc. London: Longmans, Green, & Co., 1892. Pp. 11-13 to 119.

*Suggestions as to the Technique of Intestinal Anastomosis.* By H. Horace Grant, M. D., of Louisville. [Reprinted from the *Annals of Surgery*.]

*Poisoning by Creasote.* By W. Freudenthal, M. D., of New York. [Reprinted from the *Medical Record*.]

*Some Differential Points in the Diagnosis of Syphilis and Tuberculosis, with Illustrative Cases.* By Prince A. Morrow, M. D. [Reprinted from the *Journal of Cutaneous and Genito-urinary Diseases*.]

*Cystic Degeneration of the Muscular Fibers of the Heart. A Form of Disease hitherto Undescribed.* By Arthur V. Meigs, M. D. [Reprinted from the *Transactions of the College of Physicians of Philadelphia*.]

*A Series of Fifty Consecutive Operations for Cataract.* By Robert L. Randolph, M. D., Baltimore. [Reprinted from the *Johns Hopkins Hospital Bulletin*.]

*Bemerkungen zu dem Artikel des Herrn Gleitsmann: "Ein neues und einfaches Verfahren zur Beseitigung der unangenehmen Folgezustände nach Gebrauch der Galvanoëautik bei Hypertrophien der Nase."* Von W. Freudenthal, M. D., New York. [Aus der *New Yorker medicinischen Monatsschrift*.]

*Elements of Materia Medica and Therapeutics, including the whole of the Remedies of the British Pharmacopœia of 1885 and its Appendix of 1890.* By C. E. Armand Semple, B. A., M. B. Cantab., M. R. C. P. Lond., etc. With Four Hundred and Forty Illustrations. London: Longmans, Green, & Co., 1892. Pp. xxxii to 480.

*A Manual of Practical Obstetrics.* By Edward P. Davis, A. M., M. D., Clinical Lecturer on Obstetrics in the Jefferson Medical College, etc. With One Hundred and Forty Illustrations, two of which are colored. Philadelphia: P. Blakiston, Son, & Co., 1891. Pp. 8-9 to 298.

*Spectacles and Eyeglasses; their Forms, Mounting, and Proper Adjustment.* By R. J. Phillips, M. D., Instructor in Diseases of the Eye, Philadelphia Polytechnic and College for Graduates in Medicine, etc. Philadelphia: P. Blakiston, Son, & Co., 1892. Pp. viii-17 to 97.

*The Ætiology, Diagnosis, and Treatment of the Prevalent Epidemic of Quackery.* (An Address delivered, by invitation of the Faculty of the Medical Department of the Buffalo University, before the Graduating Class, May 3, 1892.) By George M. Gould, M. D., of Philadelphia. [Reprinted from the *Medical News*.]

## Miscellany.

**Does Organic Disease of the Heart preclude the Use of Chloroform in Parturition?**—This was the title of a paper read by Dr. T. Ridgway Barker at a meeting of the Philadelphia County Medical Society held on April 27th:

In entering upon the discussion of a subject of such paramount importance to mother, offspring, and obstetrician, one can not lay too much stress at the very outset upon the axiom that "A good remedy will fail of its effect if not properly administered." This fact must be kept uppermost in our mind if we would avoid fatal results, not due, however, to the employment of the agent, as some would make it appear, but to the lack of attention and care exercised in its administration. That there is a radical difference between surgical and obstetrical anaesthesia (analgesia) goes without saying. If we consider for a moment the stages of anaesthesia, which differ only in the profoundness of the impression—first, sopor; second, stupor; and, third, stertor—we can not fail to notice that in analgesia one rarely has occasion to carry the effect beyond the first degree (sopor), while in the surgical variety we are obliged to advance beyond this and keep the patient in the second stage, or that of stupor, thus markedly increasing the gravity of the prognosis.

In this connection, let us devote a moment's consideration to the progressive effect of chloroform vapor upon the nerve centers of the cerebro-spinal system, beginning, as it does, at the inferior extremity of the cord, sacro-lumbar, and gradually extending its paralyzing influence upward until it reaches and expends its force upon the medulla oblongata. These well-established clinical observations having been verified by physiological experiment, we are justified in putting them to practical use. What other agent, may be pertinently asked, can relieve—aye, abolish—pain so quickly and safely, yet leave reflex muscular contractility unimpaired, as chloroform? Ether and ethyl bromide have found favor with some practitioners, but neither can displace chloroform.

Fordyce Barker states in his writings: "I may say here that I have long regarded chloroform as the best and safest anaesthetic in obstetrics, and that since 1850 I have used no other."

The danger from the employment of chloroform in this department of medicine depends more upon the carelessness with which it is administered than to any toxic effect inherent in it. The four cardinal points to be borne in mind when giving this anaesthetic are: First, plenty of pure atmospheric air; second, liberation of a small amount of the vapor at a time; third, attention to the respiration; and, fourth, frequent observations as to the force and frequency of the cardiac action. That the recorded cases of death have been due in a great measure to saturation of the residual air in the lungs to a fatal degree can scarcely be doubted. A few deep, forced inspiratory efforts will quickly produce such a condition. Withdrawal of the agent under these circumstances can not prevent the further entrance of the chloroform vapor into the

circulation, for it already fills the air-cells. Nor will attempts at artificial respiration prove effectual, since but a small quantity of the residual air can be forced out of the lungs, while that which enters fails to sufficiently dilute the vapor owing to the tardiness of diffusion. Let us not suppose, however, that because we administer to the parturient female small amounts of the drug continuously, therefore no risk is incurred, for experiments directed to solve this important question go to prove that even small doses, when continuously inhaled, tend to produce dangerous, and at times fatal, cardiac exhaustion. Far different is the result when given intermittently, as is the unalterable rule in obstetrics. Should we seek authority for the statement that the dangers from the careful administration of chloroform in labor are too insignificant to warrant its refusal, we have only to turn to the *American System of Obstetrics* to find therein the following: "The danger when chloroform is used only to the extent of mitigating or abolishing pain in childbirth is practically *nil*." Lusk, quoting from Bert's experiments, states that "chloroform might be intermittently administered for an indefinite period with safety." These remarks do not apply to its use in the third stage of labor, for, as is well known, after delivery of the child it is likely to occasion relaxation of the uterus, thus favoring post-partum hemorrhage.

Offering the foregoing as a preface to my remarks on the judiciousness of employing chloroform when the parturient female suffers from organic cardiac disease, it now remains for us to consider the effect of parturition upon this enfeebled circulatory organ, thereby securing a scientific basis for our conclusions. In the first stage of labor we find the muscular contractions confined to the uterine muscular layers and directed toward overcoming the circular fibers of the cervix, while in the second or propulsive stage not only does the uterus exert its power to the utmost, but also the abdominal and respiratory muscles are brought into action by the will of the parturient in her efforts to expel the fetus. The diaphragm is forced down and its movements paralyzed by the female holding her breath.

The other respiratory muscles are likewise unable to act, and hence imperfect oxygenation of the blood results. As a consequence, the cardiac movements are accelerated, greater resistance is met with in the pulmonary and aortic circulations. Moreover, a tendency exists to venous congestion, as evinced by the hue of her face and swollen veins.

Owing to the excruciating pain experienced when the head passes through the cervix, the parturient is further tempted to make additional muscular efforts, which only augment the difficulties met with. Under normal conditions this strain is of such brevity that it can not be considered of any importance, but when complicated by disease of the heart it is of far greater gravity. If the condition is one of fatty degeneration due to a previous pericarditis or myocarditis, resulting in faulty nutrition and enfeeblement of the heart's action, as evinced by weak impulse, venous stasis, confused and irregular sounds, anæmia alike of brain and other organs, with faintness and oppression on the slightest exertion, this interference with circulation and respiration may readily tax its powers too far, and so cause speedy death from paralysis. Here the conditions which pertain in surgical anæsthesia are absent. The indications present are to allay excessive muscular action and respiratory spasm which is threatening the over-stimulated heart.

To allow the female to continue such efforts is to permit her to commit suicide; to warn her to desist is useless when in such agony; while delay is likely to be fatal. How can we overcome this condition of nervous excitement? Can we accomplish it by the administration of chloroform? Yes; of the two evils, for we must acknowledge there is an element of risk in giving chloroform, we can only choose the lesser, and so promptly proceed by inhalation to relieve the accessory muscles of parturition of their strain. By the abolishment of pain we lessen the work required of the laboring heart, which, instead of beating at the rate of one hundred and forty or more a minute, may diminish in frequency to ninety or one hundred.

What has been said of fatty heart is equally applicable to conditions of hypertrophy and dilatation.

The equilibrium, if disturbed, is almost certain to result disastrously. That sense of fullness in the chest and oppression due to bronchial congestion, if relief is not afforded, becomes most distressing. The cyanosis from deficient aeration is greatly exaggerated, while the

insufficient blood-supply to the brain causes syncope and may be succeeded by coma if the excessive reflex disturbance be not removed. Nor are the indications for the administration of chloroform materially different in the case of females in labor with valvular disease. Whether it be mitral in the young adult or aortic in the aged primipara, the cardiac strain must be relieved if we would save our patient. As is well known, all forms of valvular disease ultimately develop a condition of ischemia on one side with corresponding low tension, while on the other side is stasis with high tension. While by compensation life may run on for years, yet, when the strain of parturition comes, it will soon be overthrown if precautions are not taken to prevent it.

Of what benefit will be our knowledge of the value of cardiac "physiological rest," as laid down by Fothergill, if we do not apply it under these conditions? We all appreciate the importance of securing "quietude of mind and body" when such pathological states exist. Then why not employ the quickest and safest means to obtain it by the inhalation of chloroform? If the danger is great from "active exercise—climbing mountains, running up stairs, lifting heavy bodies, and all kinds of exercise involving heart strain"—how much greater, aye, how immeasurably so must it be when the parturient female forces, with the anguish of despair, every muscle to its utmost in her desire to deliver her child. From a study of chloroform anæsthesia in obstetric practice we have seen how it should be administered and how it acts. Surely none will deny that in its employment under these circumstances we act otherwise than for the best interest and safety of our patient. That one may not be charged with being a blind adherent to theory, one has only to turn for support and justification to the teachings of the late lamented Fordyce Barker, who states: "It seems to be almost accepted as an axiom, with both the profession and the public, that the inhalation of chloroform is dangerous for any woman with disease of the heart. For more than thirty years I have been convinced that this opinion is quite erroneous, and I have so taught in my lectures and in former writings."

He goes on further to say: "I have seen several cases, complicated by dangerous heart lesions, which terminated favorably, as I think, solely from the use of chloroform."

Snow, likewise, is of this opinion: "In all forms of valvular disease," he says, "chloroform, when carefully administered, causes less disturbance of the heart and circulation than does severe pain." To quote from Championnière: "If," he says, "I recognized an organic affection of the heart, without pulmonary complications, I should rather give the woman chloroform than let her suffer." Were further proof necessary as to the propriety of employing chloroform anæsthesia, one might include among this group of clinical observers Vergeley, who expresses himself thus: "Diseases of the heart are not a contra-indication to the use of anæsthesia." Macdonald states: "In almost all cases of heart disease with labor chloroform has been given, and apparently with benefit, during delivery. If carefully administered, I think it can not but be useful in all cases." Since such eminent authorities advocate its employment, can we justify ourselves in refusing our patients the benefit and comfort this agent affords? What is the danger from chloroform compared to the state of exhaustion and collapse into which the parturient female will inevitably fall? If this heart is forced to the verge of paralysis from overwork and excitement, why shall we not use the means at our command to lessen that strain? Let us have a reason for the faith that is in us, and not hesitate to fearlessly employ extreme measures to overcome extreme dangers.

Chloroform by inhalation can and will, if properly administered, save the lives of parturient females, suffering from organic disease, when death seems imminent from over-stimulation of its ganglia through reflex nervous action. Organic heart disease, then, does not preclude the use of chloroform in labor, but rather is a condition calling for its careful administration.

**The Dietetic Treatment of Heart Disease.**—Dr. Felix Hirschfeld, says the *Therapeutic Gazette* for May (in an abstract of an article published in the *Berliner klinische Wochenschrift* for March 11th), while occupied with the investigation of the assimilation of corpulent people, observed that with the progressing loss of bodily weight there was also a loss of organic albumin. This loss is not prevented, or even greatly

lessened, by the consumption of larger quantities of albuminates. Every Banting process is to be looked upon as a diminished nourishment, with the added fact that the assimilation is considerably increased by great muscular exercise. The loss of albumin is greatest in the first week of Banting. With a loss of weight of from four to five pounds troy, there will be a loss of four to eight drachms of nitrogen, corresponding to thirteen to thirty ounces of muscle.

The loss of nitrogen is considerably greater when the patient is plethoric than in the case of an anæmic person.

It is remarkable that, in spite of the loss of albumin, physicians have found almost always an increase of muscular strength, especially of the heart, during gradual Banting processes.

To determine whether this would continue to be the case, Dr. Hirschfeld tried experiments upon himself and other healthy persons, and found that with their food reduced to a half or one third the usual quantity, there was no weakening of the heart; this was true of thin and not specially strong persons, as well as of those who were moderately stout and strong.

The lessening of nourishment makes also a change in the circulation. In the first place, the volume of blood is diminished, for the blood does not become more watery; the quantity is of the same concentration but smaller. With the smaller quantity of blood, the demands upon the heart are less, this bearing an analogy to cupping, in which ease the lessening is more rapid.

Another point seems even more important. Whenever food is taken, the processes of the glands and of the muscles of digestion demand an increase of oxygen, which the heart must provide by increased activity; the more frequent and the larger the meals, the higher the demands upon the heart. The slight weakening of other organs is not to be deprecated in comparison with the favorable result for the heart. For example, in the case of valvular trouble following rheumatism, it has been customary to allow but small quantities of food, but present knowledge demands that the nutrition be kept up by abundance of easily digested food, especially milk.

Hirschfeld quotes various authors who have used the milk-cure for heart trouble. This is simply a "hunger-cure," and is in general seldom used, because opposed to the prevailing idea of nourishing the organism as much as possible. He finds in the results quoted another proof of the value of diminished nourishment, another means available to lighten the labor of the weary heart. While seeking to increase the power of the heart, the course is made easier by making the demands upon it as slight as possible.

Hirschfeld thinks the strengthening of the heart-muscles by exercise, as practiced at Marienbad, is decidedly dangerous. The whole "cure" being often made in six weeks, necessitates a rapidity which is not safe. It is quite possible that corpulent persons repeating this "cure" yearly, or every second year, bring about a weakening of the heart's walls. Often these very persons, pleased with the rapid loss of weight, console themselves, as soon as their six weeks are over, with an added luxury of living and richer food. The strengthening of the heart by muscular exercise should be accomplished slowly.

In the treatment of corpulency there often occurs, in spite of the loss of albumin, an increase of muscular power, especially of the heart. The smaller amount of food produces conditions of the circulation which lighten the work of the heart.

In strengthening the heart by means of exercise, especially in corpulent persons, it only should be gradually increased. When the heart is urged to oft-repeated exertions in a short time, there is a tendency to dilatation of the heart by a weakening of the heart walls.

**The New York Academy of Medicine.**—The special order for the meeting of Thursday evening, the 2d inst., was a paper on the Conservative Treatment of Salpingitis, by Dr. Paul F. Mundé.

At the next meeting of the Section in General Surgery, on Monday evening, the 13th inst., papers are to be read as follows: On the Mechanical Treatment of Ununited Fracture of the Neck of the Femur with Traction Apparatus and Direct Lateral Pressure over the Trochanter Major, by Dr. Newton M. Shaffer; and Further Experience in the Treatment of Inoperable Carcinoma of the Uterus with Pyocyanin Injections, by Dr. H. J. Boldt.

At the next meeting of the Section in General Medicine, on Tuesday evening, the 21st inst., Dr. J. K. Crook will read a paper entitled Observations on the Diagnostic Significance of Vascular Murmurs in the Neck, based on Examinations of 1,500 Persons.

**Homœopathic Soup.**—A correspondent of the *Critic* says that the following verses were published in some newspaper—what one he (or she) does not remember—a number of years ago:

Take a robin's leg,	Set the kettle on,
Mind, the drumstick merely,	Get it well a-boiling,
Put it in a tub	Skim the liquor well
Filled with water, nearly.	To prevent its oiling.
Place it in a spot	When the soup is done,
That is cool and shady;	Set it by to jell it;
Let it stand a week—	Then, three times a day,
Three days for a lady.	Let the patient smell it.
Put a spoonful then	If the patient die,
In a five-quart kettle;	'Twas disease that did it;
It should be of tin,	But if he survive,
Or, perhaps, bell-metal.	Give the soup the credit.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

FIVE CASES OF  
THE PIN SENSATION IN THE THROAT.

BY JOHN DUNN, M. D.,  
RICHMOND, VA.

CASE I.—Miss A., milliner, aged twenty-nine. The patient complains that there is, whenever she “swallows,” the sensation in her throat as though there were a pin or the bristle of a brush sticking her. The sensation is well localized and never changes place; is referred to the right side of her throat, upon a level with the deepest part of the hyoid fossa. It is not a surface sensation, but seems to have its seat deep in the throat. This sensation is increased in unpleasantness whenever she catches cold. It never leaves her, although the pin or bristle seems to scratch the surrounding parts more at times than at others. Miss A. has no remembrance of having ever swallowed a pin or a bristle, but, from the sensation, is “certain that it must be the one or the other.” She has often swallowed crusts of bread to try to dislodge this “pin.” The sensation has existed for eight or ten years, and no treatment she has received has been able to relieve her. At times this place must ache, since Miss A. says that it gives her neuralgia down her neck to the collar bone, in the shoulder, and of the scalp behind the ear. She is constantly clearing her throat to remove this “pin.” Miss A. is anæmic, and has the appearance of being nervous and overworked. The nose is normal, except that the mucous membrane is too pale, and the middle turbinate of the right side is hypertrophied enough to lie against the septum anteriorly. The nasopharynx is clear. The left tonsil is normal. The right tonsil is somewhat hypertrophied at its lower end. The pharynx is normal, except that just behind the posterior pillar on the right side, opposite the lower end of the tonsil, is an area, about two millimetres broad and five millimetres long, which has the appearance of being slightly thickened, is slightly redder than the adjoining mucous membrane, and looks as if it might be subject to some irritation. I made a note of this condition at the time, but in no way connected it with the “pin sensation” felt so distinctly lower down. The laryngeal region was normal, except that there appeared on the right side of the epiglottis a very small, whitish area, to which some little mucus was adherent. There was no demonstrable trouble in the external canal or inner ear. There was no bad tooth. The teeth were examined because of the presence of the neck neuralgia. I took a probe and touched the tonsil of the right side. Miss A. said the trouble was lower. I then touched various points along the left side of the base of the tongue, and each time Miss A. said I had not gone far enough down. I then examined the external neck carefully, and especially the point to which the sensation was referred. Nothing abnormal could be found, except that deep pressure over the skin at one point on the side of the larynx was said to be painful, but there was no sign of inflammation to account for this. There were no enlarged glands. Examination of the lungs revealed some louder breathing than normal. Finally, the part that the hysterical element might play came up before my mind. The sensations, however, were too definite, and the patient was too willing to have anything done for relief, for me to believe that there was not some definite cause for the sensations, which I believed to be plainly reflex. I told Miss A. that I could not find anything in her throat that might cause such a sensation, but, if she would submit, I would remove everything, as far as I could, that was abnor-

mal in the throat, and that some one of these conditions might be the cause of the trouble. She was willing to submit to anything, and asked me if I would not give her chloroform and cut down on the spot she touched with her finger and remove whatever it was that was sticking in her throat. Speech, breathing, powers of deglutition, etc., were perfectly normal, and I would not leave the impression that there were any symptoms which seemed in any way to threaten life, but what there were were a constant source of annoyance to the patient. The treatment and results were as follows:

*September 28th.*—Removed the hypertrophied lower end of the right tonsil. The patient said immediately after the removal that the “pin sensation” had disappeared. I feared, however, that the disappearance was due to pain caused by removal. It proved to be so, as the “pin sensation” returned as soon as the cut place was healed.

*October 6th.*—I passed a horse-hair probang into the œsophagus, well down; opened it and pulled it out. This was done on a hint from an older physician, who took the hysterical view as to the cause of these sensations. Furthermore, her physician told me Miss A. had lateral curvature of the spine, and suggested a connection between the neuralgic conditions of the neck and this condition of the spine. Passing of the probang, however, failed to relieve Miss A.

*9th.*—Removed with a snare the hypertrophied anterior end of the middle turbinate.

*16th.*—Pin sensation still present, together with neuralgic tenderness and numb sensations in the parts supplied by the greater and lesser mastoid and auricular branches of the superficial cervical plexus; this sensation at times also goes to the parts supplied by the supra-acromial and supraclavicular branches of the same plexus.

I did not see Miss A. again until December, when she informed me the same sensations were still present. I examined the throat again, and touched with the point of a probe the small, reddened area just behind the posterior pillar, at the level of the lower end of the right tonsil. “That is the place,” said Miss A. Here, then, in this small reddened area was the origin of the sensations which Miss A. referred to a position in the neighborhood of the lowest part of the hyoid fossa of this side. I took a bent probe and touched various points in the mucous membrane below this inflamed area, as far down as the middle of the hyoid fossa. The resulting sensation was described by Miss A. as being *above* the sensations which originated from the reddened area. “The place is farther down still,” but as soon as I touched this place, opposite the tonsil, Miss A. would say, “There it is.” With the electric tip I cauterized thoroughly this area, with the result that immediate relief was experienced, and this relief lasted until the burned place healed, when the “pin sensations” returned as before. Three times was this whole area burned out with the cauterizer; each time Miss A. experienced relief until healing took place, after which the “pin would return to her throat.” Treatment has furnished absolutely no relief. On April 20, 1892, Miss A. told me that “the same pin” was in her throat, and that she suffered as much as she had before treatment was begun. There is one point of further interest in regard to the case. When this area is first seen it appears to be redder than the surrounding parts, but if it is touched with a probe it immediately becomes of a deep red, and swells from the blood sent to it, so as to be in marked contrast with the neighboring mucous membrane. I can give no explanation as to the cause of this phenomenon.

CASE II.—This case came to the clinic in November, 1891, while Miss A.’s case was still in my hands. The patient, Miss

B., aged seventeen years, complained of exactly the sensation in the left side of her throat that Miss A. had in the right—that of a pin or a bristle sticking in it. In the case of Miss B., however, this sensation had lasted only a week, and was referred to a dinner, where she must have swallowed “a pin or something like it.” The place of the sensation was again at the side of the throat behind the upper part of the larynx, and was more or less constantly present. Examination of the nose and nasopharynx revealed the picture common enough, where there are adenoid hypertrophies, enlargement of the third tonsil, hypertrophied turbinates, etc. To this it may be added that there were also enlarged tonsils; but, as these conditions had existed for years, while the pin sensation had made its appearance within a week, they were excluded from the possible causes of the trouble. There was nothing in the hyoid fossæ, nothing in the larynx, to give rise to this sensation. I told the patient that perhaps something she had swallowed had scratched the throat, and that the trouble would wear off in a few days; if not, to return. A week later Miss B. returned, saying that the pin was still there in the same place.

While making a laryngoscopic examination the mirror was pressed against the upper part of the left posterior pillar. “There is the place!” exclaimed Miss B., and touched with her finger the side of the throat opposite the thyroid cartilage. Closer examination showed just above the enlarged tonsil on the left side a small “granulation,” somewhat inflamed. On touching this with a probe the patient said that that was the place where she felt the pin. When asked, however, to swallow and then put her finger over the spot, she always carried her finger to the side of her throat opposite the thyroid cartilage, and it was here that she felt the pin sensation when the granulation was touched. The granulation, inflamed, was certainly the cause in this case of the sensation. It was removed, and the patient was told to return after a few days if she was further troubled. She did not return, and the inference is that she was relieved.

CASE III.—This case is one of a young man about thirty years of age, brought to me by Dr. Lewis Wheat, of this city. The history is as follows: A few hours before, he had between his teeth a bent pin, which, owing to his suddenly bringing his teeth together, had sprung from between them “down his throat.” He was “certain” he had “swallowed it,” for he had “looked all over the carpet” and could not find it, and then, too, he had “felt it when it went down.” And, besides, he “felt it sticking in” his throat whenever he swallowed. There was no constant pain present; no pain save a slight pricking sensation on swallowing; no cough; no obstruction to the passage of food into the stomach. The patient, however, persisted in affirming that the pin was in his throat, and would place his finger on the left side of his throat opposite the upper back part of the thyroid cartilage as the point where the pin was sticking. Examination of the larynx and the hyoid fossæ revealed nothing. (And let me say by way of parenthesis that the best way to obtain a perfect view of the hyoid fossæ, in patients where from oversensitiveness of the supralaryngeal structures, a view of them is shut out, is to make the patient laugh while the examination is being made. The fossæ then open and may be viewed in every corner.) The pharyngeal and rhino-pharyngeal examinations revealed nothing to indicate the presence of a pin. Opposite the left tonsil, between the posterior pillar and the pharyngeal wall, was a small mass of hypertrophied lymph tissue, slightly inflamed, and identical in position with that the cause of the trouble in Case I. I touched this with a probe. “That is about the place,” said the patient. To convince him no pin was there, I swabbed the area with a cocaine solution, when, after a minute, the pin sensation was gone. A moment later he said the feeling was on the other

side of the throat. “The feeling” was, however, too evidently a forced one to need attention.

CASE IV.—Dr. R. came to me saying that he had a “bristle in his windpipe.” The only symptom was a sensation of something sticking in the throat every time he swallowed. Examination of the pharynx showed a single acutely inflamed granulation of the pharynx opposite the center of the tonsil on the side upon which the “bristle” was felt. This sensation had been present several days. When this granulation was deadened with cocaine, the “bristle” could no longer be felt in the throat. The granulation was pinched with a forceps, and Dr. R. had no more trouble. The point to be noticed is, that the sensation was referred to a point at least two inches below the place from which the sensation originated.

CASE V.—Miss M. complained that she had swallowed a pin, which was sticking in her throat, and, as in the preceding cases, the pin was located in the region of the larynx. Examination of the pharynx revealed on the posterior wall an acutely inflamed granulation near the lower end of the tonsil. This was cocaineized and pinched with a forceps. The next day Miss M. returned, saying the pin was still in her throat. Examination revealed, just below the granulation I had pinched the day before, a second smaller granulation. This was pinched as the other one had been and Miss M. had no further trouble.

These five cases have been reported because physicians so frequently have patients who have “just swallowed a fish-bone,” or a “chicken bone,” or “a pin,” which is now sticking in the throat. To the physician’s eye there is no urgent symptom—no cough, no difficulty in swallowing solids or liquids, no place painful on pressure—and yet these patients insist upon the presence of the foreign body in the throat, since they “feel it every time they swallow,” for their imagination, sharpened by their ideas of choking to death, magnifies any slight abnormal sensation of the throat into a real evil. And, further, it happens sometimes that the physician, although he assures his patient that “it has gone down,” has in his mind a great deal of uncertainty as to whether it has or not.

In Cases I, II, and III the sensation was that of a pin sticking in the throat; to each patient the sensation was definitely localized in the side of the larynx. In the first case, though the probe was used extensively about the root of the tongue, the patient always said “the pin is lower yet,” while when it touched the inflamed area, although higher up, it brought forth the exclamation, “There it is!” In the last two cases the sensation could be produced by “swallowing,” but the knowledge that the act of “swallowing” would cause the sensation caused the patients to repeat continually this act to convince themselves that the pin was still present.

In Cases II, III, IV, and V the sensation was due to an acutely inflamed “granulation” of the pharynx. In Case I the sensation originated in a localized area of the post-pharyngeal wall, which area from some cause remained more or less constantly irritated. In all, the sensation could be produced at will by touching with a probe the inflamed areas, or by making the patient swallow. In the first case the nervous element may have played a prominent part. In the third case, Dr. Wheat had some years ago performed laparotomy for a wound of the intestines, and, though the operation was eminently successful, the patient

had obtained a more intimate acquaintance with his intestines than is vouchsafed most men, and it made him regard with apprehension the possibility of a foreign body finding its way into them, and thus he was willing to magnify any sensation that would seem to justify his fears.

The reason why in these cases the patients insist that the pin sensation is in the throat at the side of the larynx is probably to be sought in the facts that they know nothing of the anatomy of the throat, and that the "pin" is felt only in the act of "swallowing," when the larynx and its adjacent parts are lifted, and there is a general contraction of the muscles at the back of the throat, at which time to the patient a definite localization of the sensation in an unknown region is difficult. These cases seem to show that, in the cases of "pin sensation in the throat," the cause is a definite one and not altogether imaginary; that, in a certain proportion of cases, the cause is to be sought in the neighborhood of the tonsil, and is either an acutely inflamed "granulation" or an hypertrophy in the lymph chain behind the posterior pillars of the fauces of the side upon which the sensation is felt. These cases further show that searching will discover the origin of these sensations, and that when it is found we can state accurately to the patient the cause of the trouble, which will be more gratifying to him than to hear that "it scratched the wall of the œsophagus in going down and all will be well when the scratch heals," or something similar.

## A CASE OF SYRINGOMYELIA.

By WALTER VOUGHT, M. D.,

CHIEF OF CLINIC, DEPARTMENT OF NERVOUS DISEASES  
(CLINICAL ASSISTANT, DEPARTMENT OF GENERAL MEDICINE),  
VANDERBILT CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS.

SEVERAL points in this case make it worthy of record. The onset of the disease, the dissociation of sensory symptoms, and the fact that the syringomyelia was added on to a condition of chronic hydrocephalus, place it among the unusual cases of this disease.

The history was as follows:

William S., the second of five children, twenty-four years of age, single, and a machine operator by occupation, was first seen by me January 1, 1892. The patient's mother, who is alive, is of a nervous temperament and, while pregnant with the patient, was often hysterical. Outside of this she has always been a healthy woman. His father has at the present time tuberculosis, and seven others of his family have died of this disease.

The patient was born normally without instruments, and was a bright, healthy baby until one year of age. At this time his head began to enlarge abnormally, and continued to do so for several years. He cut his teeth without difficulty, and as an infant and young child never vomited or had convulsions. As a young child he was always sleepy, would fall asleep anywhere and at any time, and when sent out by his mother to play would sit down and fall asleep. Up to his sixteenth year there was some impairment in his gait, as he often fell in walking, and it was difficult for him to run.

At sixteen he had his first general convulsion. This was not followed by any paralysis. Soon after this he began to have momentary attacks of twitching of the right hand only, accompanied at times by the secretion of a large amount of saliva.

During these he never lost consciousness. These attacks lasted for three years and occurred at intervals of about two weeks. At the end of the three years, or when he was in his nineteenth year, he had a general convulsion. This began in the right hand and thence extended to the whole body; he bit his tongue, passed water, and slept after the attack. Since his nineteenth year these convulsions have occurred at intervals of three weeks to six weeks. In the past year they have become more frequent, and, instead of having one, there have been eight or nine at a time. The attacks are at the present time preceded by an aura of a frightened, nervous feeling and are accompanied by a cry, and immediately after he loses consciousness. Following the attacks he is very much exhausted, and for two or three days after is unable to continue at his occupation.

Six years ago, while in his eighteenth year and one year before the onset of the general convulsions, he noticed that he could not feel objects with his right hand as well as with the other. At the same time there was a loss of pain sense in the hand, for he would burn or cut himself without experiencing pain, and only by the blisters or bleeding present was he cognizant of any injury to the part. There was also loss of heat sensibility, hot and cold water being indistinguishable with the right hand. Four years ago there was added further difficulty in walking. This began on the right side and has been progressive ever since.

Three years ago numbness and weakness began in the right hand. The numbness soon extended to the right leg, and shortly after the right side of the face became similarly involved. To these symptoms was added wasting in the hands, which was of about simultaneous onset in both.

He has always complained of much headache, which has been worse in the past five years. For three weeks he has had some difficulty in his vision. He is unable to distinguish objects well at a distance, and there has been much dizziness.

He has always had rather imperfect control over his bladder. This has not been more pronounced of late.

His intellectual capacity is of a low order, and it has never been possible to teach him more than reading and writing.

*Examination* shows a short, stocky man, with well-marked hydrocephalic-shaped head. On the parts of the body where there is no muscular atrophy the muscles are well developed and firm.

*Examination of the Muscles.*—There is marked atrophy of the thenar and bypothenar of both hands, which is greatest on the left side. The muscles of the forearms are atrophied slightly and of soft, flabby consistence.

There is *main en griffe* in both hands, more pronounced in the left.

There is atrophy and paresis of the anterior portion of the deltoid muscle of the right side.

Fibrillary twitching is present in the muscles of both arms.

*Electrical Examination.*—The reaction of degeneration is present in the muscles of the thenar and bypothenar of both hands. In the anterior portion of the deltoid of the right side  $AnCC = CaCC$ .

*Reflexes.*—The tendon reflexes of the upper extremities are wanting. The knee-jerks are both exaggerated,  $R > L$ . There is ankle clonus in both lower extremities, more marked in the right.

The epigastric reflex is absent; all other skin reflexes are present.

The eye muscles are normal. The right pupil is larger than the left; both react to light and accommodation.

The muscle and stereognostic senses are good.

Ophthalmoscopic examination of the eyes was not obtained.

*Sensory Disturbances.*—Tactile sensibility is nowhere com-

pletely abolished, but over the shaded areas (Fig. 1) there is great impairment in this sense.

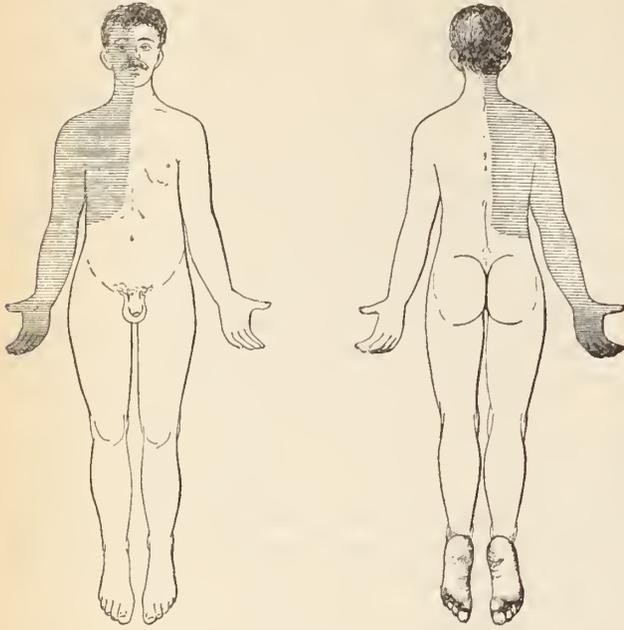

FIG. 1.

*Thermal Sensation* (Fig. 2).—Over the areas shaded by horizontal lines there is loss of appreciation of both heat and cold. Over the dotted areas there is diminished sensibility to heat. Over the areas shaded by vertical lines *sensibility to heat is lost while that to cold is retained.*

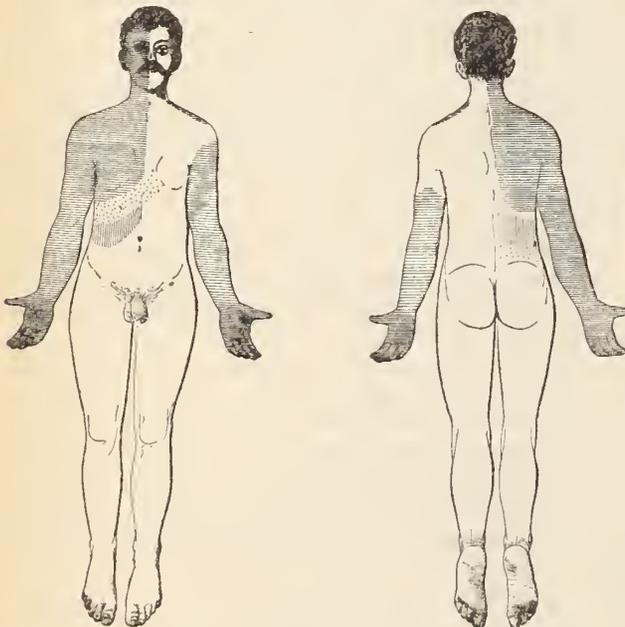

FIG. 2.

*Pain Sensation* (Fig. 2).—Over the areas shaded by horizontal lines there is complete loss of pain sensation. This area on the face and scalp is very sharply defined by the median line. Taste and smell are normal.

The patient wears a 7 $\frac{3}{4}$  hat.

He was put upon the use of potassium bromide, which postponed but did not prevent his epileptic attacks.

His general health steadily failed. On February 10, 1892,

he had convulsions for six hours, and died two hours afterward from exhaustion. No autopsy was obtained.

Reviewing the symptoms present, it is found that a healthy baby developed at one year of age chronic hydrocephalus, which continued to manifest itself by the shape of the head, mental and physical hebetude, and unsteadiness in walking until his sixteenth year. At this time epileptic convulsions appeared, and for three years were followed by attacks of *petit mal*. At nineteen years of age general epileptic convulsions began again and continued, causing death at the age of twenty-four. Six years before death the symptoms of the syringomyelia began with sensory disturbances, and three years after, the muscular atrophy appeared. Both diseases progressed, the hydrocephalus the more rapidly.

The development of syringomyelia upon a chronic hydrocephalus has been considered probable, but no case has as yet been met with by us in the literature of the subject.

The almost unique dissociation of the temperature sense is an interesting phenomenon, and but one similar case has been thus far reported.\*

The posterior columns of the spinal cord appear in this case to have been the parts first affected, which is contrary to the general rule that the gray matter of the cord around the central canal is the part primarily affected.†

12 WEST TENTH STREET.

### SOME PREVALENT ERRORS RELATING TO "EYE-STRAIN" AS A CAUSE OF NERVOUS DERANGEMENTS. † WITH ILLUSTRATIVE CASES.

BY AMBROSE L. RANNEY, A. M., M. D.

THE view that "eye-strain" may be a frequent and extremely important factor in causing many forms of nervous derangements—even in some that are quite commonly regarded by medical men as organic diseases, such, for example, as epilepsy, St. Vitus's dance, and insanity—seems to be steadily gaining ground in spite of the bitter opposition of those who have for years unsuccessfully combated this view.

So strongly have many progressive practitioners in medicine, as well as oculists, both here and abroad, been impressed of late with the wide application of this view to the treatment of obscure nervous disorders, that they are at last beginning to discard the rash and often injudicious administration of drugs that has hitherto prevailed, and to search more scientifically for the *underlying causes* of nervous diseases.

But a few months since, one of the leading medical journals of this country published in its editorial pages,‡ in strong advocacy of this method of treatment, several columns under the following heading: "A Great Medical Discovery ignored." From this editorial I quote the following paragraphs:

\* Déjérine. *La Semaine médicale*, 1891, No. 6.

† *New York Med. Journal*, Nov. 21, 1891.

‡ *Medical News*, December 12, 1891.

There are few medical truths that have been discovered fraught with more possible and incalculable good to humanity than one that is ignored by the great body of the medical profession.

There are explanations and sufficient reasons for this anomalous fact. Among them may be noted these:

1. The discovery has come about slowly and silently. It has been made by no one man and has come with no flourish of international congressional trumpeters. So softly and slowly has it crept into scientific medicine that its own advocates are but half aware of it, and do not yet realize its almost unparalleled value.

2. It is a therapeutic measure that depends for its exercise upon an exactness of knowledge of delicate mysterious physiological and psychological functions that few possess, and upon a subtle discrimination and judgment with which, by character or education, few are endowed.

3. It has the misfortune to depend for its promulgation and practical application upon the specialist, and almost upon the specialist of a specialty—and this in a profession and in an epoch in which it is fashionable to sneer at specialism, and at the specialist who dares plead for the truth he knows—and that, at first at least, only he can know.

Not long ago I received from one of the most distinguished medical teachers of this country a letter that indicated a decided "change of heart," based, as is too often the case, upon some very startling disclosures that scientific eye-tests had revealed in his own visual apparatus and that several oculists of eminence had previously overlooked. He says in this letter:

DEAR DR. RANNEY: I send you as a patient Mrs. —, a confirmed sufferer from intractable neuralgia! *Personally, I have ceased to treat neuralgia like a d—l fool.*

Gratefully yours, — —.

Most of the medical contributions that have lately appeared as antagonistic to the view that "eye-strain" constitutes an important factor in the neuropathic tendency, and that functional nervous diseases can be relieved or modified by eye treatment, are based largely upon statistics derived from the observations of those who are either manifestly ignorant of the later methods of examination or who fail to employ them from bigotry and prejudice.

It is well known by searchers of the truth that in most of our large eye dispensaries the refraction of eyes is determined chiefly by the ophthalmoscope (a rapid and very imperfect method even in good hands); that ill-fitting spectacles are commonly bought by these patients, and in consequence the glasses are not accurately centered to the pupils; and that errors in adjustment of the muscles of the eye which exist in many of the patients are not even sought for in most dispensary clinics. The multitude of patients that swarm in and out of these institutions require more time than can be bestowed upon them. They are touched up with astringents—boric acid, etc.—by the score for granular lids, corneal ulcers, etc., *without any effort to determine the underlying cause* for these common conditions (that either remain chronic or tend to constantly recur in the same individual); when in almost every case some hidden error of focus or maladjustment of the muscles of the eye is an exciting cause of these conditions, and a cure can generally be obtained by the removal of this cause.

Perhaps the most common experience that I personally encounter in my office is to have patients tell me that either their doctor or some oculist whom they have consulted has said to them that "their eye trouble is the *result* of their physical weakness and *not a cause*; that the *relief* of the eye trouble can have nothing to do with their recovery; and that all statements to the contrary are not supported by facts."

It is for the purpose of demonstrating the counter-proposition, of showing that "eye-strain" may be the *cause* of obscure diseases and not its result, and of turning, if possible, the channel of medical thought so as to benefit suffering humanity, that I raise my voice again in defense of a method of treatment that will often accomplish what drugs will not, and that is based upon science rather than therapeutical speculation and empiricism.

The few cases which I report here in detail I have selected from a very large number on my private records, in order to demonstrate most positively my view of the points at issue. They have been seen by many physicians from time to time. They are of such a varied character as to shed light upon and confirm, I think, many disputed statements. To many of these patients the verbal or written opinion of prominent medical men had been given prior to my seeing them, "that *organic disease* unquestionably existed, and that the eyes had nothing to do with the causation of the symptoms."

In some of these cases no possible explanation of the facts here recorded can be suggested, except to admit that the correction of an existing "eye-strain" caused a cessation of the leakage of nervous force that had been going on for years; and, by so doing, the sufferers had been enabled to regain their normal condition.

These patients took no drugs; they continued in their customary vocations; and they got well. All former experiments with drugs and doctors had failed to bring about a like result. Most of the females had had their wombs treated by the latest recognized methods; all had taken medicines of various kinds; and several had been pronounced by conscientious medical advisers as incurable.

Among the cases reported in this paper are four typical cases of epilepsy; several of nervous prostration of so severe a form as to justify the most serious doubts in any medical man as to a perfect recovery being possible; one case of mental collapse to an extent which rendered the patient unable to dress himself until told which article of apparel to put on first, and who would chew on a bolus of food for an hour, if not told to swallow it; one case of melancholia with morbid impulses, who walked about the streets touching every tree, lamp-post, and ash-barrel; one case of epileptic mania, for whose use a room padded with mattresses was kept; several in which confirmed inability to sleep, severe neuralgic paroxysms, ear-sickness, constant headache, etc., formed an important feature in their clinical histories; one case of St. Vitus's dance that was followed, before I saw her, by an entire loss of power in the right arm and partial in both legs; one case of terrific neuralgic paroxysms of the face that drugs would not control; and other cases of various conditions that were equally distress-

ing to the patient and that had withstood all therapeutical measures.

In the light shed upon a field of scientific inquiry by such a set of remarkable cases, is it not a justifiable source of surprise that many oculists of prominence, in full possession of the facts, refuse to-day to follow implicitly, and others even to try, a method of treatment whose details have been quite fully described in medical literature?

The sad results, viewed from the standpoint of suffering humanity, that are entailed by indifference and prejudice in men of scientific reputation can not be estimated.

By giving expression to others of their opinion concerning what they have not properly investigated themselves or will not see, thousands of sufferers are doomed to a life of misery.

Such patients naturally believe that abnormal eye-factors in their own case have been sought for by the latest methods and found to be absent by one who stands high in his profession. They quote to their friends the positive assertions of him (whom they believe infallible) that "eye-muscles are not worth investigating"; that "all deviating tendencies of the eyes are invariably due to errors of refraction"; that "Javal's instrument has been used, and that settles the question forever"; and other similar expressions, indicative either of inexperience, bigotry, or prejudice, that too often come to my own ears.

Now, may I ask what has actually been done by the oculist in many such instances to give him a basis for any of the conclusions quoted above, that lead often to despair and life-long suffering on the part of the patient?

To save time and trouble, in most public dispensaries, and, unfortunately, in the private consultation rooms of some oculists of repute, the patient is generally taken into a dark room after reading a test-card (which is often omitted), and a concentrated beam of light is first cast into each pupil with an ophthalmoscope for the purpose of determining, in an approximate fashion only, the refractive conditions of the eyes. Glasses are frequently prescribed on information thus obtained.

Then, if the eye muscles are examined at all (and they are often totally disregarded), the patient is frequently put through a series of tests that have little, if any, scientific value, and which ought to have been discarded years ago—such as following with the eyes some small object (usually the point of a pen or pencil) held in the hand of the oculist, and subsequently looking at the "line-and-dot" card at the reading point through a prism.

It is well known and generally acknowledged to-day that the ophthalmoscope is not an instrument of precision \*

\* There are two sources of error which are possible in all ophthalmoscopic examinations as a step toward the determination of refraction. The first of these is that the observer may not be able to perfectly relax his own accommodation while using the instrument. Most oculists of large experience believe that they can do this with certainty—a belief which is perhaps not always well founded. The second source of error lies in the accommodation of the patient. This can not always be relaxed by instructing the patient to look at an object twenty or more feet distant from the eye. I am satisfied that mistakes in the determination of refractive errors by the ophthalmoscope are far more frequent than are generally supposed. For the past seven years I have

when the refraction of an eye is to be positively determined. The greatest ophthalmoscopist of his day in this country tried some years ago to determine the refraction of the writer's own eyes by this instrument and made a dismal failure—as he himself had to confess after atropine was employed.

The ophthalmoscope has its proper uses and is a valuable instrument; but for the determination of anomalies of refraction it is too unreliable to be of value in cases where careful investigation is demanded.

One of the leading oculists of this city has lately written an article \* in which the remarkable statements appear that in cases of asthenopia, hypermetropia of two diopters and a half may be ignored in young subjects; that if cylindrical glasses are ordered the existing hypermetropia may be ignored; and that mydriatics may be dispensed with if Javal's instrument is employed.

The conclusions of this writer are advanced, fortunately, by him only in reference to those patients who suffer from difficulty in using the eyes (asthenopia). While few oculists of prominence, I think, will accept these conclusions from even this limited standpoint, I am personally satisfied that they are absolutely untenable if applied to more severe types of reflex nervous phenomena dependent upon eye-strain.

The author of this article can bear witness personally to the effect of spherical glasses, which caused an instantaneous cessation of all symptoms of complete nervous prostration that came upon himself gradually some twelve years ago without apparent cause. The eye-defect that existed in him had eluded the detection of several skillful oculists, and was only brought to light by the use of atropine. To spherical glasses alone he owes his present health, comfort, and ability to labor.

If it were necessary, in my judgment, to multiply illustrations here to prove that spherical glasses as well as cylindrical glasses have important curative results upon serious nervous disturbances, I could adduce hundreds of

examined the eyes of almost every patient intrusted to my care by the aid of test-type after the pupils have been fully dilated by atropine. I am not aware that I have ever lost a patient by the use of this drug. In my experience intelligent persons are always willing to submit to a temporary inconvenience for the purpose of obtaining *positive information* respecting any point that is deemed of scientific value in relation to themselves. I have personally come to regard the ophthalmoscope as an unreliable instrument for the determination of refraction. Its use is rendered compulsory, however, in very young children, and in those who, from ignorance or feeble-mindedness, are unreliable in their reading of test-type. It is generally accepted, furthermore, among our best oculists that astigmatism (a recognized source of nervous perplexity) is always estimated more accurately with the pupil widely dilated by atropine than with the normal pupil. The reasons which I have already given must suffice to explain why the use of atropine constitutes a most important preliminary step to the detection and estimation of any error in the eye muscles, although many other arguments might be brought forward to prove its advisability in some subjects. Again, the view is held that no examination for suspected muscular error in the orbit should be regarded as conclusive for diagnosis, or as a basis for any surgical procedure, until the eye has been proved to be free from refractive error, or rendered as nearly emmetropic as possible by properly selected glasses.

\* D. B. St. John Roosa. *Medical Record*, March 26, 1892.

illustrative examples from the records of my private patients. I prefer, however, to refer the reader to my brochure upon the treatment of headache and neuralgia,\* and also to one that relates to the cure of sleeplessness,† for illustrative cases that bear upon this subject.

So long as eye examinations are made in a careless and perfunctory way; so long as a careful and accurate determination of the refraction of the eyes is not made under atropine; so long as abnormal conditions of the eye-muscles are not diligently sought for by the only scientific method that has yet been devised for that purpose; so long as careful records of each test and the power of the individual eye muscles are not kept so as to admit of comparison between conditions encountered in any patient from time to time; so long as bigotry and intolerance blind the eyes of eminent men to a proper sense of justice to others; so long as the general medical practitioner neglects to study the principles of testing eyes sufficiently to discriminate between careful work and perfunctory work—so long will the treatment of nervous affections be relegated exclusively to drugs, the sufferings of thousands be unrelieved because the cause is not searched for, and the progress of medical science be seriously hampered and retarded.

I quote from a late brochure of mine the following paragraphs:

"One thing is evident—viz., the view that 'eye-strain' can and frequently does cause serious nervous conditions must be either true or false.

"If it be false, then it has made steady progress in spite of its weakness and against organized and bitter opposition; if false, then the growing list of converted advocates among the younger oculists and neurologists is incapable of explanation; if false, then the thousands of suffering humanity are deceived who believe that they have cause for the deepest gratitude in the recognition and relief of an existing 'eye-strain.' It is contrary to all precedent that a mere 'fad' should steadily flourish and gain strength year by year over a period of many years; neither does the statement that some cases have failed to be benefited by this treatment have any weight in argument. Every method of treatment of disease sometimes fails to relieve individual cases; yet no one attempts to discard all therapeutical efforts in consequence of this fact, because such a deduction would be manifestly illogical."

In the reported cases that follow, some terms are employed that may require explanation to the general practitioner, although they would be easily understood by the oculist. These are comprised in the following table:

Terms related to the focus of the eye (refractive terms).	{	HYPERMETROPIA ( <i>far-sightedness</i> ). A shallow eye (from the front to the back), causing an imperfect focus of objects.
		MYOPIA ( <i>near-sightedness</i> ). An elongated eye (from the front to the back), causing an imperfect focus of objects.
		ASTIGMATISM. An irregularly curved cornea or lens, causing distortion of images on retina.
		EMMETROPIA. A perfectly constructed eye.

Terms related to the muscles which move the eyes (muscular terms).

Various forms of glasses employed by oculists.

- ESOPHORIA. A tendency of one or both eyes to deviate toward the nose.
- EXOPHORIA. A tendency of one or both eyes to deviate toward the temple.
- HYPERPHORIA. A tendency of one eye to rise above the level of its fellow.
- ORTHOPIHORIA. Normal adjustment of the eye muscles.
- ADDUCTION. The power of the internal muscles of the eyeballs. *It varies in health between 25° and 60°.*
- ABDUCTION. The power of the external muscles of the eyeballs. *It should be 8° in health.*
- SURSUMDUCTION. The power of the vertical muscles of the eyeballs. *The right and left should be alike.*
- SPHERICAL. Ground upon a convex or concave sphere. Used to correct hypermetropia and myopia.
- CYLINDRICAL. Ground upon a convex or concave cylinder. Used to correct astigmatism.
- PRISMATIC.\* Two plane surfaces of glass meeting at an angle. The thick side is termed the base of the prism. Used to relieve errors of adjustment of the eye muscles.

\* Prismatic glasses are not only inadequate as satisfactory remedial agents in most cases, but they may be positively injurious to certain classes of patients. Strict limitations upon their field of usefulness (not generally taught) seem to be rendered probable by late investigations. A careful study of the different movements of the eyeball, and of the combination of muscles required to produce some of them, must impress even the most casual reader with the idea that an agent (such, for example, as a strong prism) which tends to restrict the movements of any one muscle may do harm if persistently worn. Some patients are peculiarly susceptible to such influences. I have encountered a large number of patients whose eyes refused to tolerate a prismatic glass. Their symptoms were at once made worse whenever they attempted to correct an existing muscular anomaly by wearing a prismatic glass. On the other hand, many patients are benefited at once by the use of prisms, and suffer no inconvenience of any kind from them. What are we to infer from this statement? Are we to surmise that the prisms were either injudiciously selected or improperly placed, simply because the patient could not tolerate them? I think not! Such might possibly be the case in the hands of a novice, but presumably it is not the case in the experience of one skilled in eye examinations. My own experience in several such instances has shown me that a tenotomy of the muscle exhibiting the greatest tension has been followed by a complete cessation of the nervous symptoms for which the patient sought relief, in spite of the fact that prisms prescribed to correct the same error have proved intolerable to the patient, and have markedly aggravated the symptoms.

There is, however, a practical and important field for prismatic glasses. *It is well to keep, as a part of a physician's office equipment, a large number of prisms of different angles.* These can be slipped into a frame with the base inward, outward, upward, or downward, as the exigencies of any case seem to demand. They may be loaned from time to time to patients, for the purpose either of verifying a diagnosis or of developing a latent muscular error which the physician may be led (by repeated examinations of the patient) to suspect. When they are well tolerated, the physician may often learn a great deal by their protracted influence. When they are not well borne, it is advisable, as a rule, to discontinue their use at once. It is often wise to prescribe a prismatic glass, also, for a class of patients who are unable (for one reason or another) to submit at the time to tenotomy. Sooner or later, I find that

\* Medical Record, June 22, 1889.

† N. Y. Medical Journal, March 28, 1891.

Several months ago, in an article published by me in reference to the causes and cure of sleeplessness, I made use of the following illustration as a means of making the bearing of "eye-strain" upon the general health clear to the reader:

Any expenditure of nervous energy in excess of that generated from day to day (irrespective of where the excessive expenditure occurs) may in time so deplete the reserve capital of nerve force in any individual as to embarrass the workings of some part or parts of the nervous system without any actual disease being present. The result of this temporary "nervous bankruptcy" is peculiarly apt to disclose itself in some derangement of the normal function of the weakest part—as an echo is heard far from the source of the echo.

Let us cite, as an apt illustration of what I mean, one of our every-day experiences:

An upright business man, with a stated income, has, from certain extravagances, etc., spent not only in excess of his income for many years, but has gradually encroached upon his capital. He grows moody, reticent, and irascible, and becomes almost imperceptibly an altered man. His friends, ignorant of the cause of the change, gradually become distant and fewer in number. Social estrangements, domestic unhappiness, a general loss of esteem, and many other complications then begin to arise day by day and month by month, until the individual falls from the high position that he once occupied with warrantable pride. Now, what has caused this fall, and what is the remedy? Unquestionably, to every thinking mind, the initial and underlying factor in all the ultimate results would be the exces-

such patients usually return. As a rule, they do so for one of the following reasons: (1) Because they have developed an additional "latent" muscular error, which the prisms naturally failed to correct; (2) because they do not tolerate them well, and are made decidedly worse by their use; (3) because they prefer a tenotomy to the inconvenience of a glass which has to be constantly worn; and (4) because they suffer from eye-fatigue on account of the disturbance to co-ordinate movements of the eyeball. There is no doubt that very many persons with nervous diseases are materially helped (if not radically cured) by the aid of prismatic glasses; but the question naturally arises to my mind in this connection, "Would they not have been more rapidly benefited and permanently relieved with far less inconvenience to the patient by tenotomy?" The view is held that a *graduated or complete tenotomy is the only means of permanently relieving abnormal tension of a muscle in the orbit*. There are only two ways of overcoming an abnormal tendency of the visual axes to deviate from parallelism whenever the eyes are directed upon an object more than twenty feet off. One of these is by the aid of a prism; the other is by tenotomy of the muscle which directly aids in producing and perpetuating the deviating tendency. Whenever prisms are prescribed, they afford relief practically in the same way as a "rubber muscle" does in orthopaedic surgery; in other words, they compel the muscle which is opposed to the base of the prism worn by the patient to overcome the antagonistic muscle, and also to so adjust the eye as to compensate for the refractive effect of the prism. They practically act, therefore, as a "pulley-weight"—a mechanical device seen in all gymnasiums. Now, if the wearing of prisms had no deleterious action upon those particular muscles, which, in each case, are not at all at fault, and if they invariably exerted only beneficial effects, this principle of treatment could be more generally applied with benefit. Even then the existence of "latent" insufficiency might, unfortunately, remain unrecognized for a greater or less period of time, possibly to the serious detriment of the patient. On the other hand, if it is satisfactorily demonstrated that tenotomy has been rendered a safe and accurate method of correcting muscular anomalies in the orbit, a fact has certainly been noted that opens a new and shorter route to relief. Such a step enables us, moreover, to decide the question of "latent" muscular defects in any given case.

sive expenditure of money. The cure, moreover, lies in stopping the initial cause, with the hope that time and prudent living will restore not only the impaired business capital, but likewise the cheery nature and honest manhood that originally gained the individual his high position, and that can alone restore it to him.

When we stop to reflect, we can understand how every letter on a printed page, as well as every object on the street, or in our homes, that we become cognizant of by the sense of sight requires a more or less perfect adjustment of the complicated muscular apparatus that so regulate the eyes in relation to each other as to enable them to see with both and yet perceive but a single image.

The total *aggregate of such visual perceptions* during the sixteen hours of each day that we use the eyes is enormous; and it means a proportionate number of accurately performed adjustments of two cameras (the eyes) upon a single object, performed often with marvelous rapidity, and involving in many of the adjustments a complete change of combinations in the eye muscles that are successively brought into play. It is not much of a task to lift a penny once, but no living being could lift a penny a million times each day.

Now, Nature has so accurately balanced the relative power of each of the various eye muscles in a perfectly constructed being, and has so beautifully constructed the eyes as regards their focus, that the expenditure of nerve power (in the case of such an individual) required to perform the necessary eye movements throughout each day is reduced to a minimum, although necessarily very large as compared with the amount expended upon any other organ in the body.

But, when the adjustment of the eye muscles or the construction of the eyes themselves is so imperfect that the maintenance of single vision (when both eyes are simultaneously used) is the *result of an excessive expenditure of nerve-force* (far greater than Nature intended in many cases), any individual so afflicted begins from birth either to draw from the "reserve capital of nerve-force" that Nature has stored up for emergencies, or the eyes must be run at the expense of a proper nerve-supply to some other part (Peter being robbed to pay Paul).

Three factors then enter into the proposition as to how long a time can elapse before the serious influences of such a leak of nervous energy will be felt in any given case where the eyes or the eye muscles are abnormal: 1. How much excess of energy over the normal amount is required to compensate for the defects connected with the sense of sight. 2. How much "reserve capital" of nerve-force the individual starts out in life with. 3. How much nerve-force the individual can generate day by day to meet the daily expenditure.

A child inheriting one hundred thousand dollars at birth could have expended upon him one thousand dollars per year in excess of his income without feeling the lack of money for one hundred years; but if the excess of expenditure be increased to five thousand dollars over his income, bankruptcy would stare him in the face when he attained his majority.

A serious defect of construction in one or both eyes, or a decided tendency of one or both eyes to deviate from parallelism with its fellow, may entail upon an individual a leakage of nervous force that is apt to produce in time very sad results upon the general health.

We are now prepared to pass to the consideration of some cases that I have selected from my case-books in order to demonstrate, if possible, beyond cavil (1) that a direct relationship between "eye-strain" and some extreme forms of nervous disturbances can exist; (2) that the correction of "eye-strain" may be followed by very marked

benefit in some instances; (3) that it is the duty of a physician to have the eyes of all patients afflicted with abnormal nervous disturbances examined early by some oculist who is familiar with and employs the latest methods; and (4) that errors of adjustment of the eye muscles are quite as important to detect and rectify as are marked errors of refraction.

CASE I.—Mr. P., aged forty-one, manufacturer, married.

*Family History.*—Both parents died at seventy-five years of age. Mother was of nervous temperament. One brother died of Bright's disease.

Patient has seven children, all unusually healthy.

*Eye Defects.*—Hypermetropia and astigmatism. O. D. + 0.50 s.  $\ominus$  + 0.75 c. axis, 90°. O. S. + 1.25 s.  $\ominus$  + 0.50 c. axis, 90°. Left hyperphoria, 4°. Esophoria, 7°. Adduction, 22°. Abduction, 4°. Right sursumduction, 2°. Left sursumduction, 8°.

*History of Case.*—This patient was brought to me by his wife from Canada at the suggestion of their physician Dr. B., who had good cause to suspect an advanced case of softening of the brain.

For several months prior to this visit the patient had taken but little if any medicine and had steadily lost flesh. His mental condition had become alarming and his doctors had practically regarded the case as hopeless. He had to be taken care of by his wife, who paid all the bills and looked after him as she would a child. While dressing, he had to be told what clothes to wear and which to put on first. At the table he would chew his food until told to swallow it. His demeanor was extremely apathetic, except at intervals when he would start suddenly from his chair, grab his head in both hands, and walk in an agitated manner about the room, complaining of great pain in his head.

For twenty years he had had severe attacks of neuralgia affecting the left eye and left side of the face, and for many years he had been annoyed by flowing of tears over the cheek in cold weather. For six years he had had marked symptoms of indigestion, flatulence, and constipation. Eating was followed by severe pain in the region of the stomach, and he had been obliged to restrict his diet for some years in consequence.

For six months prior to this visit he had not visited his place of business and had suffered terribly with insomnia. To such an extent did the insomnia exist that his wife would sit by him and fan him during cat-naps until noon of each day.

As he was not in condition to stand the excitement of a hotel, he was forced to lodge with friends where absolute quiet could be insured.

Great difficulty was experienced during my first few interviews with the patient in getting any reliable eye-tests, although his expression indicated a marked degree of left hyperphoria and esophoria.

After reading only a couple of lines on a test-card, he would leap from his chair, grasp his head with his hands, and say that he would come in the next day and read some more.

The case certainly looked most unpromising, and his mental condition was such that I could not divest myself of the belief that organic brain disease existed and that the case was probably incurable.

After several interviews and the free use of atropine to dilate the pupils, the eye-tests became more satisfactory. I advised the wife to consider the propriety of an operation for the hyperphoria with the hope of easing his pain and improving his sleep.

I distinctly impressed upon the wife the fact that I did not think this step would prove in any way curative; yet I could not but feel that four degrees of manifest hyperphoria was a

strain that ought to be at once removed—especially from so weak an invalid.

*Treatment and Results.*—As his wife expressed a desire to try what a correction of his hyperphoria would do for him, a graduated tenotomy was performed upon the left superior rectus. The result was a great surprise to his friends as well as myself.

The night following the operation he slept soundly all night. He arose the next morning, dressed himself without aid, and drank three goblets of milk before the rest of the family were up. He then sat down and ate a good breakfast, finishing as quickly as any one.

Within a week he demanded his money from his wife, saying that he would not have her pay his bills for him; and a short time afterward he began to come daily to the office from Brooklyn without any one to accompany him.

Two weeks after the operation patient reported that he "wrote a long letter (the first in over four months), that he eats well, sleeps well, takes an interest in the newspapers, and is marvelously improved in every way." A full correction of his errors of refraction was ordered and he was instructed to wear his glasses constantly.

Some weeks later a graduated tenotomy was performed on the right internal rectus for the relief of the esophoria, and the patient returned to Canada to take charge of his business.

For the past two years patient reports that he has had no return of his old symptoms, but is considerably annoyed by headache, which at times is quite severe. He has been very inconstant in wearing his glasses. This may account for the continuance of his headaches, although there is reason to suspect that some hyperphoria still remains.

CASE II. *Epilepsy and Epileptic Mania of an Aggravated Type.*—Mr. S., aged nineteen. First seen by me on November 27, 1888.

*Family History.*—Mother has frequent and severe sick headaches, and her sister is a martyr to them also. The brother and sister of the patient have headaches. The paternal heredity could not be accurately given by the mother, who brought the boy to me for treatment. No phthisical tendencies had ever manifested themselves in any of the patient's ancestry, as far as known. Every known relative on the maternal side suffers from headache.

*History of the Case.*—The patient is a tall, finely developed young man of five feet ten inches, weighing about a hundred and fifty pounds, and with a good color. His mother gives the following facts:

Up to the fourteenth year of age the patient was in perfect health. He then had his first epileptic seizure, following upon an attack of so-called "congestion of his brain," for which no cause could be found except a fall while skating. He was then at school in Paris.

Within the next year, in spite of bromides, he had three "fainting attacks," lasting an hour each.

He was then removed to a school in England, and had a number of severe epileptic seizures in spite of large doses of bromides.

In August, 1887, he was sent to America and placed in a select school, where he could be carefully watched over and his habits of life regulated. He had taken every day for the previous year not less than sixty grains of potassium bromide and fifteen grains of sodium bromide, and at times much larger doses.

During the year prior to his visit to my office the seizures had become more frequent and extremely violent—so violent that three men could not restrain the patient, and a room had been padded with mattresses and specially kept for the protection of the patient when thus seized. Into this room he would

be placed and allowed to thrash about, until attack after attack would prostrate the patient. All medical treatment seemed of no avail, and the father was asked to remove the boy from the school.

Medical advice was then taken, and it was deemed advisable to commit the patient to an insane asylum as an incurable and uncontrollable case of dangerous epileptic seizures. At the earnest solicitation of friends, the parents were urged to make a trial of the "eye treatment" in the hope that it might possibly avert so horrible a fate for the boy, even if it did not markedly affect the frequency of the fits.

As the absolute cessation of the bromides was insisted upon by myself, from the date of the first visit, the boy was with some reluctance admitted at my solicitation to a private hospital, so that he could come to my office with an attendant and be protected from injury if the fits became very frequent or severe.

A record kept by the principal of the school showed that thirty-four fits had occurred in the twelve months that preceded my care of the boy, in spite of extreme doses of bromide salts and chloral at intervals in addition to his regular daily doses.

*Eye Defects.*—On the 17th of November, 1888, patient showed normal vision in both eyes, adduction  $54^{\circ}$ , abduction  $5^{\circ}$ —, right sursumduction  $2^{\circ}$ —, left sursumduction  $2^{\circ}$ —, esophoria  $2^{\circ}$ , left hyperphoria  $1^{\circ}$ .

In accommodation, patient showed esophoria  $10^{\circ}$ .

*November 18th.*—Under atropine, patient showed a latent hypermetropia of one half diopter. Esophoria  $2^{\circ}$ , left hyperphoria  $\frac{1}{2}^{\circ}$ .

*Treatment and Results.*—The patient carried his head, as his mother said he always had done, very markedly to the left side (justifying a suspicion that right hyperphoria actually existed), and his esophoria was very palpable to a careful observer. Later on, my suspicion of an existing right hyperphoria became confirmed by most positive tests.

Here, then, was a boy who showed at the onset almost perfectly constructed eyes, with only a slight tendency inward (apparently), and a suspicion of hyperphoria, yet he was having terrific epileptic seizures that were uncontrollable by drugs. His power of abduction was low, however, and prisms of  $1^{\circ}$ , base out, were placed for twenty-four hours over each eye.

At the third visit, on the following day, he showed esophoria of  $7^{\circ}$ , and the prisms were increased to  $4^{\circ}$ .

In three days more he showed esophoria of  $10^{\circ}$ , with unconquerable double images, and the tendon of the right internal rectus muscle was freely relaxed by a graduated tenotomy. This improved his deviating tendency inward; but some esophoria still disclosed itself.

On November 24th the opposite internal rectus was likewise operated upon, and his esophoria was apparently totally corrected for some time after the operation, his adduction being normal ( $8^{\circ}$ ).

On November 27, 1888 (ten days after the cessation of bromides), the patient had a fainting attack in my office without tremor, but with a total loss of consciousness for some ten minutes. The habit of carrying the head toward the left shoulder had been persistent up to this time. An examination of the eyes disclosed a *right hyperphoria* (as was originally suspected) of quite a high degree.

From this date until February 12, 1889, patient was treated by prismatic glasses and *no return of epileptic seizures had occurred*. I then determined upon a third operation, and let out the right superior rectus as far as I deemed it wise to do so, although I failed to perfectly correct his right hyperphoria by so doing. Prismatic glasses were again resorted to, as a step toward correction of the existing "eye-strain."

The boy then returned to his former school.

On July 1st, when the *boy had passed over seven months* without an epileptic seizure, I received a letter from his mother, from which I quote as follows:

"I want to tell you how very grateful I feel for the great good you have done my boy. It is really wonderful how he has improved in health since he has been under your care. He writes me that he has not had a single attack since I left New York. This seems almost a miracle when one remembers how the boy suffered before coming to you."

On July 7, 1889, *over nine months* had passed since an actual convulsion had occurred, and nearly eight months since the "fainting attack" in my office. He had been some time without prisms or any eye treatment, when he imprudently used a lawn-mower violently on a very warm day for several hours. As a consequence, he was seized with one of his "old-time attacks," having three severe convulsions and two light ones in the next forty-eight hours. They were accompanied by marked gastric disturbance and fever.

On visiting me, I found some remaining right hyperphoria, for which I again operated upon the right superior rectus tendon.

On October 14, 1889, the patient engaged in a cross-country run of several miles, after school exercises, and became greatly overheated. He was again seized with a severe convulsion, and had two light ones later in the day. He had again marked gastric disturbance. Fourteen weeks had elapsed since the previous attack.

On December 26, 1889, the patient was again seen. He had experienced no return of attacks, was in excellent health, and had taken no medicine for thirteen months. He still shows  $1^{\circ}$  of right hyperphoria, esophoria of  $2^{\circ}$ , adduction  $58^{\circ}$ , abduction  $7^{\circ}$ —, right sursumduction  $4^{\circ}$ , left sursumduction  $1^{\circ}$ +. He is wearing prismatic glasses for  $2^{\circ}$  of esophoria.

On April 2, 1892, this patient reported last at the office. He is still wearing  $2^{\circ}$  prism for the remaining esophoria. He had passed *over ten months without an epileptic seizure, and only one attack had occurred in nearly two years*.

Now, what has been done for this boy thus far by "eye treatment?" He has already passed nearly four years without recourse to poisonous drugs; he has been saved thus far from a life in a lunatic asylum and restored in usefulness and health; he has had, except on three occasions, complete immunity from his horrible disease in spite of the total cessation of bromides; he has returned to his former association with his school companions; and he is today able to go about without an attendant, or the dread of impending disaster and possible confinement.

He has happily learned, I trust, that excessive and violent exercise is dangerous to his comfort, as it tends to cause an epileptic attack, and also to derange his digestive apparatus seriously. Had it not been for such extreme imprudence, he would probably have been entirely free from attacks during the past year.

Do we know that this remarkable change is due to the eye treatment? Most certainly!

The patient had never before passed so long a time without attacks as he has since eye treatment was begun, although he had been constantly drugged, according to the most approved fashion of the present day, for his epileptic seizures. He had found in the bromides for some years the only refuge that medicine offered to keep these frightful attacks within bounds that did not seriously endanger

life. He naturally felt, as did his parents, that to let go that anchor was to drift beyond aid into hopeless despair. When, therefore, I stopped his bromides at the first visit, every one concerned (the patient, his parents, his friends, and myself) felt quite sure that, unless something was done as a substitute for the drugs, the fits would surely become more frequent and severe. This substitute for drugs took the form of an operation for what I deemed the exciting cause of the attacks. Another operation was done on the corresponding muscle of the opposed eye, as soon as the necessity for it became apparent. Then we felt comparatively safe, and the patient could await with greater safety the effects of prismatic glasses.

CASE III. *Chronic Epilepsy (of Twenty-four Years' Standing).*—This case is of great interest if taken in connection with the case that precedes it. In this instance five years and nine months of immunity has followed eye treatment and the cessation of all drugs.

Mr. H., aged forty-three, merchant, began to have severe epileptic fits when seventeen years of age. Had masturbated when a boy, and had been addicted in later years to excessive venery.

*Family History.*—One brother is a confirmed dipsomaniac; the father died of paralysis; one sister is a victim to sick headaches; no phthisis has existed in the family, so far as could be ascertained.

*History of the Case.*—The epileptic seizures of this patient varied in frequency from two or three a week to one in three months. He came under my care in 1871 (when twenty-eight years old), and was treated by me for many years with enormous doses of the bromides of potassium and sodium. These salts reduced the attacks to about four a year. Stopping the bromides invariably increased the frequency of the attacks.

*Eye Defects.*—In January, 1886, his eyes were examined after his return from an extended residence in the South. He showed under atropine a latent hyperopia of 2.50 D., and also a manifest esophoria of 4°. Subsequently several degrees of "latent" esophoria also manifested itself.

*Treatment and Results.*—Partial tenotomies were performed upon both interni, and hyperopic glasses were given him. Since the first operation (January, 1886) he has taken no bromides and has not had a convulsion. He has twice been at "death's door" with fevers, but he has shown at no time any epileptic tendencies.

It may be asked, "Can this be done for the relief of every epileptic?" I would reply, "By no means!"

Some epileptics owe their disease to depressed fracture of the skull, a tumor, a cicatrix, or some other form of direct irritation of the brain itself. Others, who were undoubtedly affected with epileptic seizures as the result of eye-strain only at the onset, fail to apply for the relief of that defect until after they have been drugged with bromides and chloral for many years to an extent that has seriously undermined the recuperative power of the patient. Bromides may likewise have impaired the normal sensitiveness of the retina, as well as the tendency of the ocular muscles to accurately adjust the eyes for visual images. In many other ways these drugs sometimes so complicate matters as to make improvement slow and complete recovery improbable in spite of the satisfactory removal of the original eye defect.

When a house has been partially burned, no one expects that putting out the fire will at once restore the house. It does, however, prevent further damage, and materially decreases the time and cost demanded for its restoration. Hence it is always deemed imperative to extinguish the fire without unnecessary delay.

We must all admit, I think, that epilepsy is certainly the gravest of all the functional nervous maladies, and that it is, as a rule, incurable by drugs; hence, as I have remarked in a previous discussion concerning this subject, "one radical cure of epilepsy without the aid of drugs offsets a thousand failures as a scientific proof of a discovery."

It may be well, however, for me to mention in this connection a few of the reasons why, in my judgment, the treatment of the eyes has totally failed, in the hands of some observers, to relieve or modify some nervous conditions that had withstood judicious medication for years; and why it is that subsequently, in more experienced hands, treatment of the same patients directed to their eye muscles has led not infrequently to the happiest results.

(1) I would call attention to the fact that *preconceived notions about old methods must be abandoned without prejudice* when a new method is to be tried.

(2) Each observer must, of necessity, make himself *thoroughly familiar with all the details of the method* which he proposes to employ before he is competent to decide *pro or con* respecting its merits. This can not be done exclusively by reading. No one can describe with a pen the many intricacies that are apt to arise in solving complex optical problems. It is certainly not beneath the dignity of even an eminent man to learn (by personal observation of the work of another whom he perhaps thinks is misled, and by timely suggestions thus obtained) how facts that bear upon successful treatment may be determined that were, perhaps, at first obscure and difficult to ascertain.

(3) With a full knowledge of the method, its intricacies, and its difficulties, *conclusions should never be too hastily arrived at* in any given case. It is always "better to be sure than sorry." Those who have had the largest experience may occasionally make mistakes in judgment when a peculiarly complex problem is presented for solution.

(4) The old methods of testing the eye muscles will have to be abandoned at no distant date. A "phorometer" is now essential to all accurate work. Moreover, the separate muscles should be individually tested and their power accurately measured.

Not long since a physician who had twice collapsed from nervous prostration at the very threshold of his professional labors came to me for advice. He showed at intervals an apparent condition of equilibrium in the orbits, but welcomed prisms for a deviating tendency of one eye above its fellow, and improved rapidly under their influence. Within a week he showed unconquerable double images without his prism, and a radical step for the correction of his vertical strabismus was advised. At the advice of friends he then consulted an oculist of international repute, who not only failed to recognize the fact that the

patient saw double images, but even pronounced the eyes normal in their adjustment. The description by the patient of the rough and unscientific tests upon which that judgment was made showed clearly that the oculist was either woefully negligent of his obligations to the patient or incompetent to decide the point at issue.

Another patient upon whom I have lately performed a graduated tenotomy of the external rectus muscle with the happiest results (as it brought about a rapid and complete restoration to health), came to me originally with an eye that diverged at times, when her vision was not attentively engaged, almost to the outer canthus; yet she bore a certificate from one of the leading oculists of America that she had no defect in the refraction or adjustment of the eyes, and that her terrible headaches and difficulty in using her eyes required only constitutional treatment.

*CASE IV. Chronic Epilepsy (apparently Cured by Glasses alone).—*Mr. T., aged thirty-five years, clerk. This patient was sent to me from a neighboring State as a chronic epileptic. He stated, at his first visit, that "he could remain in New York only a day or two, and *simply wanted to see if his eyes had anything to do with his epilepsy.*"

He was a clerk in a store and had had severe fits quite frequently.

The full details of his family history, frequency of attacks, medicinal treatment, etc., were not taken at that time by me, and can not therefore be given here.

*Eye Defects.*—Without atropine this patient showed a marked myopic astigmatism in each eye that was apparently corrected by  $-2.75$  c. axis  $180^\circ$ . Under atropine a latent hypermetropia of  $+1.50$  s. was also found to exist in addition to the astigmatism.

*Treatment and Results.*—Glasses were ordered for each eye from the following formula (in April, 1890):

$$-2.75 \text{ c. axis } 180^\circ \text{ } \ominus \text{ } +1.00 \text{ s.}$$

The patient also showed esophoria of four degrees with the glasses that insured a full correction of his refractive errors.

In discussing the question of treatment with the patient he was told to wear his glasses constantly, and, if the fits continued, to return for a correction of the esophoria. I impressed upon him the fact that the use of atropine might have to be repeated, and that I could not hope and did not expect that the glasses alone would exert any very marked influence upon his epileptic seizures. I impressed upon him the fact that after wearing his glasses for a month or two it was possible that his apparent error of adjustment of the muscles might be modified somewhat. He left my office with instructions to abandon all drugs: to keep a strict record of all his epileptic seizures, whether light or severe; and to return later for further eye treatment in case the seizures continued to be frequent or severe.

Since that interview about twenty-six months have elapsed. During this time I have heard from him several times through patients that he has sent to me and once or twice by letter. Last week one of his friends reported that never since he had worn the glasses that I ordered for him had he been attacked with an epileptic seizure of any kind. This report was a verbal one that this patient had intrusted him to deliver to me. He is still a clerk in the same store, and uses his eyes constantly in his business.

*CASE V. Chronic Epilepsy, with Serious Mental Deterioration as the Result of the Administration of Bromide Salts.*—Mr. H., aged twenty-four, single, manufacturer.

*Family History.*—Father has a nervous temperament. Mother has gout badly and defective eyes. Paternal grandfather died of bowel trouble. Paternal grandmother died suddenly from some unknown cause. All paternal uncles and aunts, seven in number, lived to be from seventy-five to ninety years of age. Maternal grandmother died of phthisis and insanity (after childbirth), and was nineteen years in an asylum. One of her sisters died of phthisis. One maternal aunt died of phthisis at sixteen years of age. Maternal grandfather had gout terribly, drank heavily, and died of paralysis.

*Eye Defects.*—This patient showed an enormous amount of unilateral astigmatism. Right eye  $+0.50$  c., axis  $90^\circ$ . Left eye  $+4.00$  c., axis  $180^\circ \text{ } \ominus \text{ } -1.00$  c. axis  $90^\circ$ . Esophoria  $11^\circ$ , adduction  $35^\circ$ , abduction  $3^\circ$ , right sursumduction  $4^\circ$ , left sursumduction  $4^\circ$ .

*History of the Case.*—Patient was perfectly healthy until he went to Exeter to fit for college. While in Exeter he had several epileptic seizures.

He had no special aura, but usually bit his tongue.

Had masturbated before his attack, but has not since.

He then entered Harvard and stayed a year. He had, he thinks, four attacks during that year, during which he took no medicine.

He left Harvard in June, 1885, and in September, 1885, he went into the draughting-rooms of his father's factory. For eighteen months he took no medicine, and in that time had several attacks.

While in Cuba in 1887 he had a bad attack and began taking bromides. Within two months, while in Mexico, he had two serious attacks, cutting his chin badly in one and knocking out a front tooth in another.

He then came to New York and consulted an eminent neurologist, who increased his bromides and put him on restricted diet. He had only one severe attack and one of *petit mal* during the next year, but his mental condition became seriously impaired.

When he came to me his whole appearance and manner showed markedly the poisonous effects of the bromides. His face was covered with acne. His mental condition was so bad that an interested conversation was almost impossible. In fact, it had become so alarming that his father, with tears in his eyes, said that although he was his only son, he would rather see him dead than in his present condition.

*Treatment and Results.*—All bromides were at once stopped. A full correction of his astigmatism was given for constant wear, and graduated tenotomies were performed on both internal recti for the relief of his esophoria.

During the first six months of treatment, while his glasses were being changed and operations performed, he had five attacks—four very light ones and one medium attack. All of these occurred after excessive indulgence in rich and indigestible food late at night, and one after indulging in too much alcohol.

*During the past eighteen months he has had no attack of any kind.* He has been actively engaged in business and has gained twenty pounds in weight. He has regained perfectly his mental condition; travels without an attendant, runs a yacht, and is considered perfectly well by his parents and physician.

(To be concluded.)

**The Kings County Medical Association.**—The next meeting of this society will be held on June 14th. The leading paper of the evening will be presented by Dr. Thomas H. Manley, of New York, on The Therapeutical Value of the Mercurial Salts in Surgery. The association will then take a recess until the second Tuesday in October.

## ATHETO-CHOREIC MOVEMENTS.

BY JOHN FERGUSON, M. A., M. D. TOR.,

L. R. C. P. EDIN., L. F. P. S. GLAS.,  
DEMONSTRATOR OF ANATOMY, WINTER SESSION, AND  
LECTURER ON NERVOUS DISEASES, SUMMER SESSION, UNIVERSITY OF TORONTO.

THE subject of athetoid and choreic movements is a highly important and engrossing one. Little by little, progress is being steadily made on the morbid anatomy and pathology underlying these movements. In all conditions of brain pathology, and in the varied symptoms resulting from these morbid cerebral changes, many cases must be carefully collected and collated with each other before any definite conclusions can be deduced from the observed anatomical changes. The lesion must be limited to one special part of the brain in order that exact opinions may be formed. Should there be structural change involving two portions of the brain possessing well-known and different functions, the study becomes more complicated by the mixing of the resultant symptoms. If, however, the morbid process extends into parts of the brain of unknown, or slightly known, functions, it is quite impossible to disentangle the varying features of the symptom group, and say what is due to the pathological changes affecting one or other of the parts. Taking the contents of the cranial cavity as a whole, there are many sections whose functions are extremely obscure. A definite lesion, then, of any part of the central nervous system, where the symptoms have been carefully noted *intra vitam*, is of the utmost importance as a means of guiding medical science one step farther in the pursuit of information bearing on the question of the localization of function, and, consequently, clearing up points in diagnosis.

It is a well-known fact that after some attacks of hemiplegia these athetoid or continuous and choreic or jerky movements come on. Another fact is that these movements may continue after the paralysis has passed away. From this we conclude that the source of irritation must be located somewhere else than in the motor areas or tracts of the brain, but yet so placed as to indirectly affect these. W. R. Gowers, in his work, says: "Regarding the nature and position of the disease causing these disorders of movement, we have as yet but little pathological evidence. The symptom is observed after recovery from the paralysis, and hence in patients who for the most part live on and pass out of observation. But two ætiological facts are of great significance. The first is, that these disorders of movement are far more frequent after cerebral softening from vascular occlusion than after cerebral hæmorrhage. The second is that they follow hemiplegia far more frequently when this comes on in infancy or childhood than when it comes on in adult life. Regarding the seat of the lesion which gives rise to these symptoms, the facts are too few to permit of accurate generalization. In most of the recorded cases the disease has been situated either in or outside the optic thalamus. Since the optic thalamus is not in the motor path, disease limited to this must produce the symptoms indirectly by disturbing the function of the motor cortex."

At a meeting of the American Neurological Society Dr. G. M. Hammond reported the pathological findings in the original case of athetosis on which Dr. W. A. Hammond's

description of athetosis was based. The portion involved in the lesion was a lengthy one in the antero-posterior direction, parallel in its short axis with the internal capsule. Its posterior end had invaded the stratum zonale of the thalamus in its posterior half of the internal capsule. In its anterior extension it had crossed the capsule, invading the posterior third of the outer articulus. The author called attention to the fact that the motor tract was not implicated in the lesion, and argued that this case was further evidence of his theory that athetosis was caused by irritation of the thalamus, the striatum of the cortex, and not by a lesion of the motor tract. Dr. Spitzka reported a case in which the lesion was found in the same situation as in Dr. Hammond's case. Dr. E. C. Seguin also gave a paper on athetoid and choreic movements in a patient. The post-mortem revealed a glioma of the left thalamus and internal capsule, the movements having been on the right side. The author's views were that all cases of athetoid and choreiform movements following hemiplegia were due to injuries of the thalamus and adjacent capsule.

To the foregoing cases I shall now add the details of one that was under my own observation in which the athetosis was well marked and was not clouded by any other motor or sensory disturbances.

The patient was a tall, thin man, of about thirty years. On December 3, 1890, I saw him for the first time, and made the diagnosis of diabetes mellitus. For this he was under treatment to the time of his death, in January, 1892.

In the early part of July, 1891, he was taken ill with the continuous movements of his right arm and leg, which lasted unabated to the evening of his death. The movements were slow and continuous, rather than short and jerky; and in these respects more closely resembled athetosis than chorea. The movements of the arm, hand, and fingers were extensive. The arm would be carried with a steady swinging motion round behind the back, up over the neck and head, and round to the front again. Flexion, extension, abduction, and adduction of the fingers would succeed each other in endless rotation.

There were no sensory disturbances other than the existence of neuralgic pains. The knee-jerk was wholly gone on both sides, and sexual power was equally lost.

The post-mortem was made about twelve hours after the death of the patient. The brain, cerebellum, medulla, and pons were removed for examination. The left thalamus opticus presented the appearance in its substance of an old but distinct blood clot. Around this clot there were evidences of degenerative changes, the thalamus being much reduced in consistency. The changes in the left thalamus were both gross and minute. The above conditions were visible to the naked eye. Under the microscope both fresh and hardened sections revealed abundant signs of degenerative changes. This was very patent in the region of the pulvinar. No definite histological characters could be made out in either the central gray matter or in the stratum zonale, due, no doubt, to the softening caused by the irritation of the clot.

The commissura mollis was not invaded, and the right thalamus perfectly normal. The disease had not extended outward so as to involve the internal capsule, with the slight exception of a very small amount of degeneration that extended for some distance upward in the most anterior part of the capsule; or in that part which constitutes the anterior peduncle of the thalamus, by means of which it is brought into direct connection

with the frontal lobe. Along the inferior peduncle of the thalamus which joins it with the temporal lobe, degeneration could be traced for only an exceedingly short distance. No pathological changes could be discovered in the lenticular or caudate nucleus. The floor of the fourth ventricle was examined, but with negative results.

In this case there are several features of extreme importance. First, we have the positive existence of athetosis. In the second place, the occurrence of both gross and microscopic changes in the left thalamus. Thirdly, the entire absence of any diseased conditions in the motor tract, either cortical, capsular, crustal, or pyramidal. And, finally, the important fact that there were no sensory derangements.

How are we to account for the athetoid and choreoid movements in these cases of lesion in the thalamus. It would be somewhat beyond the object of this paper to quote from all the cases that have been reported to show the constancy of disease in the thalamus in such cases. Gowers believes that disease limited to these ganglia causes the movements by indirectly irritating the motor cortex. Ross says, in his work on nervous diseases, that it is not easy to give reasons why choreiform movements are so liable to occur when the lesion is situated in the region of the posterior external optic artery. Two probable explanations of these clonic spasms suggest themselves. The first is that fibers connecting the cerebrum with the cerebellum are injured by these lesions, so that the regulation between the tonic (cerebellar) and clonic (cerebral) actions of the body is lost. The second is that the spasms are caused by partial injury of the fibers of the pyramidal tract, which regulate the fundamental movements of the body. The fundamental actions are regulated from the convolutions near the longitudinal fissure. Fibers from these convolutions would descend on the inner side of the internal capsule, and consequently on the side in contact with the thalamus. They would therefore be more liable to injury, or irritation, in disease of the thalamus than the fibers lying more external.

With regard to these views of Dr. Ross, it may be remarked that though the latter might explain some of the cases, it could not explain the one I have recorded in this paper, as the internal capsule was entirely free from disease of any kind, and therefore the fibers governing the fundamental movements could not have been in any way interfered with. The former view is negated by my case also, as there was no disease or degeneration in the peduncular fibers leading to or from the cerebellum. It is not possible to say whether or not Gowers's view is true, as the thalamus is so extensively connected with the cerebral cortex. My own view is that the gray matter of the thalamus must be regarded as cortical in function, and therefore an originator of nervous energy, and not merely a transmitter by means of the numerous bundles of fibers connecting it with other portions of the central nervous system. If it originates movements, when diseased, they partake of the purposeless character of athetosis or chorea. In the case now recorded there was no motor paralysis; but the athetoid movements were greatly increased by all attempts at definite voluntary actions. This fact alone, taken in conjunction with the other considerations of positive disease in

the thalamus, while there was no disease elsewhere, goes to show that the thalamus must have some regulating function to fill toward our voluntary motor impulses. When this regulating function is lost, we are able to originate movements, but no longer able to so harmonize these movements as to execute a regulated and purposive work by their aid. I would therefore regard the thalamus opticus as an originator of movements; and, secondly, as a regulator, in some way, of the movements emanating from other motor areas. The thalamus may have other functions besides the above; but I think the two mentioned can be safely inferred from my case.

## PHTHEIRIASIS CILIORUM.

BY CHARLES W. ALLEN, M.D.,  
SURGEON TO CHARITY HOSPITAL, ETC.

In the *Journal of Cutaneous and Venereal Disease* for July, 1886, I reported a case of pediculi upon the eyelids. I had observed the condition a number of times previous to this, and have seen quite a number of instances since; still, the location must be considered an unusual one in comparison with phthiriasis pubis. The parasite is the same in both situations. I have not yet met with an instance of the pediculus capitis located upon the ciliary margin of the lids. Nor have I seen the nits of the head louse upon the lashes. The following case, just observed in my service at the hospital, has one or two points of interest:

Dora K., twenty-one years old, was admitted with multiple chancroids and one indurated sore upon the vulva. She also presented a pigmentary syphilide upon the neck.

Five weeks ago she noticed something on the eyelashes and tried to wash it off, thinking it was dried secretion. There has never been the slightest itching, or symptom of irritation of any kind referable to the lids or eyes, and, as no complaint was made by the patient, she had already been in the hospital for some time before the attention of the house staff was directed to the quite extensive deposit of eggs upon the lashes. Even then the pediculi themselves were seen with difficulty, so closely were their flat bodies applied to the margin of the lid.

My method of treatment consists in removing all the pediculi and their nits at a single sitting by mechanical means, stripping off the hairs with a small, sharp-pointed forceps, which will permit the nit to be drawn the whole length of the hair without making traction enough to pull the lash out. The pediculi cling so tenaciously to the hair whose follicle furnishes the receptacle for the animal's head that in removing them the hair is often sacrificed. The farther back the body of the louse is grasped, the more readily is its hold relaxed. In this case about a dozen pediculi and probably fifty nits were removed. The removal having been accomplished, attention must be directed to the axillæ and pubic region. Pediculi are almost invariably found in both these situations, and often too in some other portions of the body. I have seen them as far down as the ankles. Removal with the forceps can be practiced here as well, unless the pediculi are too numerous; then a chloroform spray, inunction with mercurial ointment, appli-

cation of strong bichloride solution (1 to 100), or petroleum, staphisagria, sabadilla, etc., will be required.

In regard to the frequency of phtheiriasis ciliarum, much depends on the source of statistical information. Jullien says it occurs but once in five thousand cases of eye diseases seen in clinics, while out of five thousand nine hundred and seventy-four eye cases seen at the Good Samaritan Dispensary, in this city, during 1891, where most of the patients are Russian Poles, there were no fewer than eighty-five instances of pediculi of the eyelashes, or fourteen per mille. Subjects of this affection do not come much to the dermatologist, and are discovered by the general practitioner, often only by accident.

696 MADISON AVENUE.

### A CASE OF OBSTRUCTION OF THE SUPERIOR VENA CAVA.

By A. O. PFINGST, M. D.,  
HOUSE SURGEON, LOUISVILLE CITY HOSPITAL.

On October 11, 1891, an apparently healthy man, forty-five years of age, was admitted to the surgical ward of the City Hospital, complaining of a sense of pain and weight in the neck, and a feeling of fullness over and between the orbits on assuming a stooping posture, which he attributed to a blow on the occiput received a month previous.

On examination, a point in his skull was found somewhat depressed, but no symptom whatever of compression was present; and if there was at this time any interference in the circulation, it was so slight as to be overlooked. He was thought to be feigning sickness, and was consequently discharged by the visiting staff officer.

On November 27, 1891, this being about a month after his discharge, he was readmitted to the hospital, when there was a decided cyanotic condition of the upper extremities. The external jugular vein on each side was very much dilated, but non-pulsating. As this condition grew worse, the subclavian vein became similarly involved. His neck gradually became larger, as did also his arms and hands, both being decidedly cyanosed, but not œdematous.

The lower extremities were never affected. The patient has grown gradually weaker, suffering more or less from insomnia, with considerable cough and impaired digestion. His principal symptom, however, was a feeling of dizziness upon stooping or on muscular exertion, or, as described by the patient, as a feeling as if there was a rush of blood to the front of his head which caused a dizziness and partial blindness.

The previous history of the patient is good, having always been a stout, healthy man, accustomed to leading an active life. He had an attack of pleurisy on the left side, for which he was aspirated in December, 1890. Outside of this and the blow on the head, he gave no other history, having no specific history.

On physical examination, the apex beat of the heart was found displaced to the left and downward somewhat, the impulse having a heaving character. There was no heart murmur. The pulse was full and strong. The lungs showed no abnormality. The cause of the obstruction is very obscure. No pulsation could be detected by pressure between the intercostal spaces to indicate an aortic aneurysm, and there was no bruit discernible by the use of the stethoscope. There was no pain or sense of constriction in the chest or elevation of temperature to indicate a mediastinal tumor of some other character, nor was there

any dullness on percussion over the region of the superior vena cava.

The attack of pleurisy, which occurred on the left side, could hardly be considered as a cause for this disturbance on the right side. The condition could be brought about by a vaso-motor disturbance, although such a disturbance is usually more general. By the exclusion of these probable causes and by the progressiveness of the case, it leaves a thrombosis of the superior vena cava as the most likely cause. The patient was on no medicinal treatment until December 23, 1891, when he was put on full doses of bromide of potassium until symptoms of bromism were produced. There was from this on an apparent improvement in his condition for several days, his neck becoming smaller, as also the varicosities, while the cyanotic condition almost entirely disappeared.

When the effect of the bromide had worn off, however, the same conditions were again present, and they have grown gradually worse until at present the least exertion causes a blueness of almost the entire face. For the past two weeks there has been an overflow of the blood of the upper extremities, evidenced by a varicose condition of the superficial veins of the abdomen, with the flow of blood toward the lower extremities.

### A PRECOCIOUS DEVELOPMENT.

By W. R. HOWARD, M. D.,  
FORT WORTH, TEXAS.

On the 16th of April, 1891, Mr. H., of Zephyr, Brown County, Texas, brought his son to my office by request. The boy was born on October 20, 1887, and was at this time three years and a half of age. He was born in Mills County, Texas, and his age is sworn to before the county clerk at Goldthwaite, the county seat.

He is three feet ten inches in height; waist measure, twenty-eight inches and a half; circumference of head, twenty-one inches and a half; neck, twelve inches; arms over biceps, ten inches; calf of leg, eleven inches and a half; weight, sixty-six pounds. Hair on his head very thick and dark; eyebrows heavy; downy moustache; hairs under arms, about the nipples, and on the lower half of the abdomen; heavy growth of hair on the pubes; penis and testicles those of an adult, well developed. Glans penis naked, and during erection the penis is four inches and a half in length and four inches and a half in circumference.

His body and limbs are well developed; pulse rate, 84; respiration, 18; respiratory and circulatory organs, normal. He has a deep bass voice; face, teeth, and mental development those of a child.

I have had his photograph made and present him to the readers of the *Journal* in representation of the production and resources of Texas, the greatest State in America.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 11, 1892.

NEW MEXICO AS A RESORT FOR CONSUMPTIVES.

DR. A. PÉTIN has contributed to the *Journal of the American Medical Association* a strong commendation of New Mexico as offering peculiar advantages to certain classes of consumptives. He states that a great variety of climatic conditions can be found in that Territory, but that which has pleased him best is found in the southern and southwestern counties; he has observed there the most sunshine, a minimum of humidity, and the least amount of dust in the air when put in motion by the winds. This latter feature of dust-laden winds was, in his experience, a troublesome one along the Rio Grande, in the valley of which there was almost always a dust, "brought by the river, which is so fine as to fly at the smallest breeze." Malaria was also reported along that river by some of the older residents. Not until he found the district in which are situated the San Augustin plains was Dr. Pétin quite satisfied. At Las Cruces he found some cases of cured consumption in permanent residents of that part of the country, some of whom, when they first came to the San Augustin plains, had not been able to walk alone. Most of them had speedily begun to improve, and had been in the enjoyment of good health ever since. "There is a peculiarity in this country," he says; "no sooner does any one get there than *he begins to feel happy!* The amount of rain in three years was an average of about four inches a year. Fogs are entirely unknown, and very seldom is there great wind. There is plenty of game of all kinds, good fishing, and beautiful shade trees at the foot of the mountains. There any patient can sleep out of doors eight months in the year without fear of taking cold."

These plains have an altitude of 4,800 feet above the sea, and are surrounded by mountains from 1,200 to 1,500 feet higher. The water supply is unsurpassable. There are mineral springs, one of which contains a large proportion of iron and manganese, and others have various sulphates in unusual quantities. The plain is quite level, 170 miles long by 80 miles wide, supporting the palm, the cactus, the Panama plant, and an endless variety of flowering vegetation, "with every kind of flowers all the year round." The temperature is most even, averaging about 62° F. all the year through, with hardly any snow-fall in the winter. When the snow does fall it does not last more than an hour or two. The soil is porous and absorbent, so that there is no ponding of rainfall and no malaria. Exercise on horseback or in any kind of vehicle can be had at all times.

Dr. Pétin has traveled extensively in Central America and South America, as well as through the Pacific and Western States of our own country, and was for a time a resident of

Colorado; but all these places, many of them very interesting and attractive, fail, he says, to combine the same number of advantages for the cure of the invalid that are afforded by the sheltered yet elevated plains of southwestern New Mexico. According to his experience, there are few sections that are at all available to consumptives where life can be passed in the open air to the same extent as in the San Augustin valley. And it is probably this opportunity for open-air life, together with the dry and rarefied atmosphere, that contributes to that feeling of "happiness" or exhilaration spoken of as being so common among those who have recently come to those plains. The bounteous sunshine is agreeable also to almost all visitors from the East, and the "tonic effect of hope" adds its influence when the patient sees that his old habits of expectoration, cough, and embarrassed respiration have been broken in upon.

POST-FEBRILE INSANITY.

DR. HENRY M. HURD read a paper on this subject at the recent annual meeting of the Medical and Chirurgical Faculty of Maryland. The *Maryland Medical Journal* for May 28th contains the full paper, in which the author mentions the recorded cases, from Chomel's, in 1834, to the present time, and reports three cases observed by himself and Dr. Thayer at the Johns Hopkins Hospital. Of the three new cases, one was a case of melancholic insanity coming on during convalescence after typhoid fever; the second was one of insanity developing from pneumonia, with systematized delusions originating in the delirium of fever; and the third was one of maniacal excitement following the removal of two diseased ovaries. In this last case there was incoherence lasting several months, after which complete recovery took place. The second case—not a hospital case—was marked by hallucinations, and delusions affecting the patient's husband; she believed that he and the female nurse had improper relations in her presence, and her embitterment against him became so extreme that she was placed in an asylum. After a year of confusion and delusions recovery set in, and she was restored to perfect mental balance.

Dr. Hurd offers the following suggestion as to an improved classification of post-febrile mental disorder: 1. Cases of insanity following shock. 2. Those developing from diseases due to specific poisons—such as puerperal fever, pneumonia, uræmia, and the exanthemata. 3. Those originating from nervous exhaustion and anæmia. In this group will be found those insanities, secondary to fever, that are an expression of an exhausted physical state; they take the form of delusions of apprehension and fear, hallucinations of sight and hearing, and perversions of taste and tactile sensibility, at times going on to stupidity and mental impairment.

Out of twenty-three cases that have been adequately reported, eleven were of typhoid origin. In four of these delirium was present during the attack; in seven, after it. Eight patients recovered, two died, and one remained insane. The pneumonic cases were two in number, one occurring during the pyrexia and the other after it. Both patients recovered after a

tedious convalescence. Nine of the twenty-three cases were subsequent to surgical operations, and the mental trouble came on at about the ninth day in several of them. In four cases there was excitement, in five there was depression; four patients recovered, four died, and one remained insane.

The author attaches no small importance to the treatment of typhoid fever with cold baths, and considers that it is one of the notable features of that method that so few of the patients develop acute head symptoms. Another suggestion offered by Dr. Hurd is that the patient after febrile disease is very frequently insufficiently fed—with perhaps at the same time insufficient quiet, too many friends or “callers,” and a premature sitting-up—and the prolonged abstention from food becomes the determining factor of mental impairment. The term “post-febrile insanity” should, in the author’s opinion, be restricted to cases that follow upon exhausting attacks of fever or upon operations and the like, and should not embrace the prolonged delirium that is engendered by toxic conditions.

### MINOR PARAGRAPHS.

#### CHEAP STERILIZED MILK FOR TENEMENT-HOUSE BABIES.

An experiment is about to be made, during the coming hot season, in providing sterilized milk for the poor in the vicinity of the Good Samaritan Dispensary. Some charitably-minded ladies and others began in 1891 the operation of a sterilizing plant as a means of teaching the tenement-house population on the east side that something could be done for the protection of infants against some of the germ diseases incident to the hot weather. This plant has been allotted a room at the dispensary, and milk devoid of germs will be sold below the cost of production, so as to enable it to compete with unsterilized milk.

#### THE KELVIN.

A NEW electrological term is the “kelvin.” Says the *Electrical World*: “The commercial unit of electricity, formerly known as the Board of Trade unit, is hereafter to be called the kelvin.” The English Board of Trade has taken formal action advocating the new term. This unit is one kilowatt hour—that is, one thousand watt hours. The new name is derived from the title of the well-known Sir William Thomson, now Lord Kelvin.

#### ITEMS, ETC.

**The Medico-legal Society of Chicago.**—At the annual meeting, held on June 4th, officers were re-elected as follows: President, Judge Oliver H. Horton; vice-presidents, Dr. Daniel R. Brower and Dr. James Barry; treasurer, Dr. Joseph Matteson; secretary, Dr. Archibald Chureh.

**A New Medical College in Chicago.**—The Clinical College of Medicine and Specialty Hospital is the title of an institution recently organized in Chicago by a company of physicians. Dr. J. E. Harper is the president and Dr. S. A. McWilliams the secretary.

**The Honorary Degree of LL. D.** has been conferred on Dr. Fessenden N. Otis by Columbia College.

**The Medical School of Columbia College.**—It is announced that Dr. T. Mitchell Prudden has been made professor of pathology.

**The Death of Dr. William R. Birdsall** is announced as having taken place on Tuesday, the 7th inst. Dr. Birdsall was forty years old and a graduate in medicine of both the University of Michigan and the College of Physicians and Surgeons.

**The Death of Dr. Charles E. Delavergne, of Brooklyn,** took place last Saturday from diphtheria. He was born in Brooklyn about thirty-five years ago, was educated at the Polytechnic and the Long Island College Hospital, taking his medical degree in 1878. He was ex-president and councilor of the alumni of the latter college, and a lecturer on practice for the summer term. He was secretary of the Medical Society of the County of Kings for several years and a member of the Board of Pharmacy of the same county. He was formerly surgeon of the Thirteenth Regiment, N. G. S. N. Y., and a member of a great number of societies, clubs, etc. He was a general practitioner of unusual prominence for one of his years, with a special tendency toward diseases of the throat and chest.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from May 29 to June 4, 1892:*

MACAULEY, C. N. B., Captain and Assistant Surgeon, is granted leave of absence for three months.

HUNTINGTON, DAVID L., Major and Surgeon, having reported in accordance with Par. 9, S. O. 107, c. s., Headquarters of the Army, is assigned to temporary duty in charge of the office of the Medical Director, Headquarters Department of Arizona, pending the absence of the Medical Director, Colonel JOSEPH R. SMITH, Surgeon.

O'REILLY, ROBERT M., Major and Surgeon, Fort Logan, Colorado, is granted leave of absence for fifteen days, to take effect in the early part of next month.

WALKER, FREEMAN V., Captain and Assistant Surgeon, Fort D. A. Russell, Wyoming, is granted leave of absence until June 30th instant, to take effect on arrival at Fort D. A. Russell of Captain JULIAN M. CABELL, Assistant Surgeon.

#### Society Meetings for the Coming Week:

MONDAY, June 13th: New York Academy of Medicine (Section in General Surgery); Lenox Medical and Surgical Society (private); New York Ophthalmological Society (private); New York Medico-historical Society (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private); Baltimore Medical Association.

TUESDAY, June 14th: Delaware State Medical Society (first day—Dover); New York Medical Union (private); Kings County Medical Association; Medical Societies of the Counties of Chemung (annual—Elmira), Chenango (semi-annual), Delaware (annual), Erie (semi-annual—Buffalo), Genesee (annual—Batavia), Livingston (annual), Onondaga (annual—Syraeuse), Oswego (annual—Mexico), Rensselaer, St. Lawrence (semi-annual), Schenectady (semi-annual—Schenectady), Steuben (annual—Bath), Warren (annual—Lake George), and Wyoming (Warsaw, N. Y.; Newark, N. J., and Trenton (private), N. J., Medical Associations; Baltimore Gynecological and Obstetrical Society; Northwestern Medical Society of Philadelphia.

WEDNESDAY, June 15th: Minnesota State Medical Society (first day—St. Paul); Delaware State Medical Society (second day); Northwestern Medical and Surgical Society of New York (private); New York Academy of Medicine (Section in Public Health and Hygiene); Harlem Medical Association of the City of New York; Medico-legal Society; Medical Societies of the Counties of Alleghany (annual) and Tompkins (annual—Ithaca), N. Y.; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, June 16th: Minnesota State Medical Society (second day) New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, June 17th: Minnesota State Medical Society (third day); New York Academy of Medicine (Section in Orthopaedic Surgery); Baltimore Clinical Society; Chicago Gynecological Society.

SATURDAY, June 18th: Clinical Society of the New York Post-graduate Medical School and Hospital.

## Proceedings of Societies.

### AMERICAN MEDICAL ASSOCIATION.

*Forty-third Annual Meeting, held in Detroit on Tuesday, Wednesday, Thursday, and Friday, June 7, 8, 9, and 10, 1892.*

The President, Dr. HENRY O. MARCY, of Boston, in the Chair.

**The Case of Dr. Potter, of New York State.**—The meeting was practically opened by the session of the Judicial Council on Monday, to consider the matter of charges against Dr. W. W. Potter, of Buffalo, late president of the Medical Society of the State of New York, and two years ago Chairman of the Section in Obstetrics and Gynecology of the American Medical Association. Dr. Potter has been a permanent member of the association for fifteen years, and heretofore his rights as a member have never been questioned. At the annual meeting at Washington last year he was elected by the association as one of its trustees. This was the signal for the preferment of charges against him as a member of the unaffiliated New York State society. Instead of the presentation being in writing, as the by-laws require, the charges were made verbally, and were not reduced to writing until two weeks after the adjournment of the meeting. The Council then referred the matter to Dr. N. S. Davis, of Chicago, as a committee, who brought to the meeting on Monday the decision of Dr. Potter's ineligibility, and this decision was sustained by a vote of seven to three of the Council. This nullifies the action of the association in electing Dr. Potter to the trusteeship, and virtually, if not actually, expels him from membership. Of course it must affect in a similar way all other members of the dissenting New York society who belong to the association, and logically disfranchises all who believe that its present code of ethics is antiquated and worn out. They include a large number of its most influential and valuable members, and, judging from the expressions of discontent which are heard on all sides, the issue may be more serious than was expected by those who have precipitated the disturbance.

The meeting was formally opened on Tuesday morning with an address of welcome by Dr. Walker, chairman of the local committee.

**The President's Address on the Evolution of Medicine** was then read. He had observed that the wise student profited by the history of the past, and drew inspiration from its pages as he confronted the present and with earnest endeavor shaped the future. We were too apt to forget the past in our exultation over the achievements of our own time. We should not forget that much that was appropriated by us as modern had been quite clearly comprehended by our predecessors.

Concerning the status of the association, it had been wisely enacted that it should consist largely of delegated members, thus making it a representative body. As such, it was the exponent of the thought and progress of the medical profession of the United States. Such an organization needed its inherent law, or code of ethics. This determined only in a general way the proper relationship of the members of a great profession to each other and to the body politic, but it had furnished for many years, and was likely for years to come to furnish, a question for discussion upon which able and honest men differed. A distinction should be made alone between ignorance and knowledge, for it was only fair to grant that considerable classes of men devoted to a common calling must be adjudged alike honest, and that their own selfish interests in the attainment of

success in any given profession must be determined by the adaptation of what they considered the best means to a given end.

The warping of the judgment by conservatism and prejudice had oftentimes in medicine, as in the allied professions, retarded rather than encouraged independent original observation and research. The lines of future progress must be based upon scientific data, upon the abolition of -isms and -pathies, and upon the introduction of a more or less accurate interpretation of scientific laws as to the proper treatment of disease. The so-called homœopathic school of medicine owed its existence largely to two factors—unreasoning prejudice in the minds of a narrow, conservative medical leadership, which called forth the sympathy of the public, and an appreciation of the advantages obtained by public sympathy and the determination to make the most from a haughty, supercilious assumption of superiority by its critics. Under competent leadership there had resulted the most popular homœopathic school of medicine, with a four-years' graded course of instruction, with restrictive, critical examinations in all the fundamental branches of medical science, until the homœopathic part had been reduced to a mere addendum to the section of materia medica. Homœopathy had been given an opportunity to demonstrate its alleged superiority in the great universities of Europe, and the result had been that its professorships there were vacant and that one must come to the Modern Athens of America if he would learn of the development of the new art. As the indirect outgrowth of sectarian medicine and its influence upon the profession in a general way, the anomalous condition of the Medical Society of the State of New York was mentioned, under the leadership of men who openly declared that the future progress of our profession demanded the abandonment of restrictive rules of polity. This society had withdrawn from affiliation with the association. The speaker, after diligent inquiry during the past year, especially in New York city, had heard only universal deprecation of the present society relationships of the profession, coupled with the pronounced opinions that the time was ripe for early readjustment and harmony. He had hoped that this greatly to be desired end would be consummated during the period of his administration, and advised moderation in the council of the association, that such an end might be attained. The outgrowth of the differences in New York had been the development of the New York State Medical Association, which was entirely in harmony with the national organization. The formation of the American Congress of Physicians and Surgeons, composed of societies of limited membership and including members who were devoted to special lines of work, was approved of and believed to be helpful, especially to those who were bound by the common tie of special study and research; but neither this nor any other similar society should overshadow the work of the American association, which was the representative body of the entire American medical profession. The interest of the State societies in the national association, especially in the East, was not so great as it should be. It was suggested that measures be instituted for developing a much closer relationship between them than now existed.

The condition of the *Journal of the American Medical Association* was believed to be entirely satisfactory, but it should be our aim to make it the leading journal of the world. It was believed that too much time in the general sessions of the association was wasted in the discussion of subjects of minor importance. Encouragement should be given on all sides to the work that was done in the sections, for here was where the chief power of the association should be felt.

The valuable work of the American Academy of Medicine in stimulating an appreciation of the value of a thorough pre-

liminary training prior to the study of medicine was acknowledged. The publishing of the details of surgical operations in the daily press was deprecated. The importance of developing and encouraging State medicine was forcibly dwelt upon, and in particular the necessity for the revision of the coroner laws in the different States.

The question of intemperance was one that was engaging the attention of many physicians, and the organization which had been effected among physicians for the study of this subject and the best methods for its repression was commended to the sympathy and attention of the members. The organization of a national board of health, with a secretary who should hold a position in the Cabinet of the President, was believed to be a great desideratum. The bill that was at present before Congress for the prevention of adulteration of food and drugs was also heartily commended. The great value of intercommunication of thought between physicians of all nations, as exemplified in the ten International Medical Congresses of the past thirty years, was regarded as a happy evidence of progress in medical science. The great progress which had been made in bacteriology and preventive medicine was also deemed a subject for grateful felicitation. Allusion was made to the losses of the association and the world in the deaths of members during the past year. Special mention was made of the deaths of four ex-presidents, Dr. Campbell, Dr. Storer, Dr. Bowditch, and Dr. Richardson.

Dr. MURDOCK, of Georgia, moved that the president's address be referred to the Committee on Publication for consideration of its recommendations. Seconded and carried.

Dr. GIBSON, of the navy, moved that letters of condolence be sent to the families of all the ex-presidents who had died during the past year, and added to the list of deaths mentioned in the president's address that of Dr. Brodie, of Detroit.

Dr. BRAY, of Canada, president of the Canadian Medical Association, was introduced to the meeting, and an invitation was extended by him to the members to attend the next meeting of its sister organization.

**The Secretary's Report** was read by the secretary, Dr. W. B. ATKINSON, of Philadelphia. An important point in it was the question as to the status of delegates from societies other than State medical societies. The by-laws recognized only those who came from duly accredited State societies, and it was recommended that other societies should come into sufficiently close relations with the State societies, or that an amendment to the by-laws should be made whereby the members of such societies could become eligible for membership.

**The Report of the Committee on Sections** was read by Dr. MARSHALL, of Chicago. It was urged that the association appreciate the importance of developing the work of the sections, some of which were suffering from lack of interest and enthusiasm. An amendment was proposed (as a substitute for an amendment offered last year by Dr. Culbertson) that each section have an executive committee composed of three members to serve one, two, and three years, respectively, and that as these members retired their places should be filled by the retiring chairman of the section, the committee subsequently being supplied with membership in that way. The committees of the sections collectively should constitute a nominating or executive committee which should nominate officers of the association.

This motion caused a most intense and heated discussion, in which, but for the admirable and temperate chairmanship of Dr. Willis P. King, of Kansas City, Mo., the meeting would have been strongly suggestive of pandemonium. The amendment was finally adopted with the exception of the last clause.

**The Committee on Public Health** reported that a bill had been introduced into both houses of Congress proposing a

bureau of public health, with a presiding officer who should be a member of the Presidential Cabinet.

**The Report of the Judicial Council** was read by the secretary of the association. It was occupied entirely with a statement as to the relation of Dr. W. W. Potter to the association. [The facts in the case will be found in the first portion of this report.]

Dr. REYNOLDS, of Kentucky, moved that the report be laid upon the table. Seconded.

Dr. N. S. DAVIS, of Illinois, objected that a report of the Judicial Council was final, and could not be debated or laid upon the table.

Dr. REYNOLDS then moved that the case of Dr. Potter be referred back to the Judicial Council, with a request that the causes for its action in this matter be specified. This was ruled out of order, and the secretary read the by-law defining the finality of the action of the Judicial Council.

Dr. REYNOLDS then appealed from the decision of the chair to the association as an authority superior to the Council.

Dr. GIBSON, of the navy, rose to a question of privilege, and declared, amid much excitement and many interruptions, that the status of permanent members who had registered year after year and against whom no charges had been preferred during that period, as in the case of Dr. Potter, could not be legitimately acted upon by the Council as it had done in the case of Dr. Potter. He cited the precedent of the case of the members representing the navy who were refused recognition at the meeting in New York in 1880 by the Council, but Dr. S. D. Gross objected, the association unanimously sustained the objection, and the members were received. The meeting sustained the chair in the ruling that the action of the Judicial Council was final.

**The Report of the Committee on the Pan-American Medical Congress**, to be held in Washington, in September, 1893, was read by the secretary-general, Dr. C. A. L. Reed, of Ohio. An organization had been effected, a bill for the incorporation of the Congress had passed the United States Senate, and was now in the House. The members of the association were appealed to to register as members of the Congress. The secretary of the association read the names of the members who had been appointed to the committee on nominations.

Dr. VAN DERVEER, of New York State, asked for information as to the present status in the association of members of the Medical Society of the State of New York, who were also permanent members of the association. The action in reference to Dr. Potter had made their standing indefinite, and he desired to know whether their membership, which in some cases had extended over many years, was now to be considered invalidated. He expressed the belief that but for the action of the Council in the case of Dr. Potter, the differences between the association and the New York State society would have been adjusted in the course of the coming year.

Dr. DAVIS, of Illinois, repeated the statement that all such matters were adjudicable by the Judicial Council alone and without debate. If the by-laws were wrong they should be changed, but as they stood at present the matter was not under discussion.

Dr. C. A. L. REED, of Ohio, moved that the inquiry of Dr. Van Derveer be referred to a committee to be appointed by the chair, to report, if possible, to the present meeting.

Dr. HEMENWAY, of Illinois, moved as a substitute that the matter be referred to the Judicial Council, to be reported on tomorrow.

Dr. REYNOLDS, of Kentucky, moved as a substitute that the Judicial Council decide whether permanent members were eligible to office, and whether the accepted registration of such mem-

bers, year after year, should not be taken as evidence of their rights and privileges as members of the association.

Dr. KING, of Missouri, proposed as a substitute that a committee of five be appointed by the association to confer with five members of the Medical Society of the State of New York to discuss the question proposed by Dr. Van Derveer, and report upon that and all kindred issues at the next annual meeting of the association.

Dr. DAVIS proposed as an amendment that five members of the New York State Medical Association be added to this committee of conference.

Dr. KING replied that he thought no assistance from the New York State Medical Association was needed in the matter, there being no question concerning its status in the association.

Dr. HEMENWAY objected to Dr. King's substitute, believing that it did not cover the original motion. The substitute was accepted in lieu of the original motion.

Dr. GIBON moved as an amendment to the substitute that those members of the Medical Society of the State of New York who had registered should be entitled to all the privileges in the association which they had heretofore enjoyed pending the decision of the question at issue. This proposal met with the almost unanimous approval of the meeting.

Dr. TRUAX, of New York State, believed that the New York State Medical Association should have a voice in the settlement of this question, and that five of its members should be added to the proposed committee. The previous question was then called for, and was put and carried. Dr. King accepted the amendments proposed by Dr. Gibon and Dr. Truax.

**The Address in Surgery** was delivered by Dr. JOHN B. HAMILTON, of Chicago. The subject was *The General Principles of the Surgery of the Human Brain and its Envelopes*. The diseases and injuries of the seat of the soul could never be a matter of indifference to the physician or surgeon; mental diseases must occupy the highest place in pathological study. Though injuries to the cranium had long been the subject of surgical measures of treatment, the brain itself had seldom received such attention. Numerous quotations from the ancient writers were made, showing the methods of treating cranial injuries which were in vogue among them. The present century had the benefit of the knowledge of past ages in respect to this department of surgery, but it had also improved vastly upon them, and would transmit to posterity a precious inheritance that it had developed and acquired.

The term "cerebral localization" was criticised as inapt in reference to the diagnosis of disease and injury of the brain. Diagnosis was difficult according to the location of the brain lesion. With some lesions the symptoms were too obscure to admit of accurate diagnosis. Oppenheim had formulated the proposition that in cases in which there were rhythmic contractions of the velum palati, the vocal cords, and the muscles supplied by the lower branches of the facial nerve, without accompanying eye lesions indicating the presence of a tumor, there was probably a purulent center resulting from encephalitis. The causes of abscesses of the brain were now definitely known to be directly infectious, except when there were infected emboli, and in most cases they followed aural or ethmoidal disease or traumatism. Robin had also observed that such abscesses were seldom uncomplicated. They had frequently been successfully treated by trephining, incision, and drainage.

Horner's conclusions from the consideration of the reports of a hundred cases of intracranial abscess due to aural disease, nine operations, and ninety-one necropsies were given in detail.

An abstract of the recent literature was also given, with reference to the subject of cerebral injuries and intracranial hæmorrhage. Asepsis and drainage were the principal factors

in the treatment of such conditions, and a number of most interesting cases were quoted in which a correct diagnosis as to the seat of the lesion had been followed by a successful operation and the recovery of the patient.

Cases were also quoted in which a correct diagnosis of tumor of the brain had been made, the cerebral and cerebellar tumors being usually associated with optic neuritis and in some instances causing epilepsy.

Cerebral injuries in the new-born, due to pressure, had been recently studied to a certain degree, but the results of operative interference had as yet been negative.

Craniotomy for intracranial pressure, incorrectly termed craniectomy, was also an innovation of importance. Lannelongue, the author of the operation, had performed it twenty-five times, without very definite results as yet.

Spinal laminectomy had recently been proposed by Tuke as the ideal surgical measure for the relief of intracranial fluid pressure. This would seem to be a reasonable procedure before performing the more radical operation of craniotomy. Trephining for mental disease had recently been revived as an operative procedure, but doubt was expressed as to the permanency of benefit to be obtained by it. The same could be said with reference to a similar method of treating epilepsy. Horsley and Agnew believed that five years should elapse after an operation for epilepsy before a conclusion should be reached as to the status of the subject of the operation.

Intracranial neurectomy had also recently been performed in a number of instances for the relief of neuralgia and paralysis, and such operations would occasionally offer good prospects of successful result. Thus it would be seen that much progress had been made in brain surgery, but much still remained to be perfected.

(To be concluded.)

## Reports on the Progress of Medicine.

### OTOLOGY.

BY CHARLES STEDMAN BULL, M. D.

**A Case of Living Larvæ in the Ear.**—Baxter (*Arch. of Otol.*, xx, 1) reports a case of a man, aged thirty-four, a farmer, who stated that, four days previously, a fly had crawled into his right ear. He removed the dead fly, and there was no feeling of pain or discomfort until two nights later, when the ear commenced to bleed, and at the same time an intense pain began. On inspection, the auricle was found red and swollen, the bandage was saturated with blood, and the meatus was full of squirming larvæ. The ear was immediately syringed with warm water, and twelve larvæ were thus removed. The auditory canal was abraded throughout its entire length, and the membrana tympani was red, inflamed, and macerated, but not perforated. At the end of a week the hearing was normal, and all appearances of inflammation had subsided. The larvæ averaged six mm. in length and two mm. in breadth. They were of a yellowish-white color and filled with blood. They remained alive for over twelve hours in the water to which about three per cent. of chloroform had been added.

**Operative Measures for the Relief of Impaired Hearing.**—Deuch (*Arch. of Otol.*, xx, 1) reports four cases of suppurative inflammation of the middle ear in which improvement in the hearing followed incisions through dense membraniform adhesions surrounding the ossicula and their articulations. He recognizes the fact that every case of impaired hearing due to suppurative inflammation in the middle ear can not be improved by operative interference. In none of the cases reported were the operations followed by inflammatory symptoms, and the pain in all was insignificant. He concludes that it seems but just, in

any case where there is a possibility of improvement by simple operative measures not attended with risk, to give the patient the benefit of the doubt, after explaining that the matter of improvement is a matter of conjecture. In cases, also, not dependent on suppurative disease, but upon eatarrrhal inflammation, with the formation of adhesions within the tympanic cavity, he thinks it justifiable to open the tympanic cavity, using antiseptic precautions, and to attempt the liberation of the ossicular chain, either by disarticulation of the incudostapedial articulation, or the division of existing adhesions, or by Miot's *brisement forcé*.

**A Blow upon the Ear followed by Death in a Week.**—Heiman (*Arch. of Otol.*, xx, 1) reports the following interesting case: A soldier, aged twenty-one, had been struck on the left side of his face and ear, which caused severe vertigo. The blow caused severe hæmorrhage from the ear, which, however, came on forty hours after the blow. The ear had previously at times discharged pus. The patient died delirious on the seventh day after the injury. The autopsy showed pachymeningitis interna purulenta diffusa, numerous small subarachnoid hæmorrhages, hyperæmia of the substance of the brain and its membranes, and circumscribed basilar meningitis. A decolorized thrombus was found in the superior longitudinal sinus, and dark-red thrombi were found in the transverse sinus and internal jugular vein. Three small openings were found on the inner surface of the pyramid which led to the tympanum. The upper surface of the mastoid was found sclerosed, and here there were several small softened areas containing pus and particles of bone. The tympanum and mastoid process were filled with thickened pus. In the mastoid were several large cavities containing pus. Pseudo-membranous bands were found in the middle ear, and the mucous membrane was ulcerated. There was a small perforation in the anterior part of the drum-head.

**A Rare Case of Auditory Reflexes.**—Steinbrügge (*Arch. of Otol.*, xx, 1) reports the case of a man, aged forty-four, who suffered from a remarkable reflex spasmodic condition, involving the respiratory apparatus in particular. This spasm follows every sort of sensory, optical, and auditory impressions of a sudden character; the patient moves both legs in a kicking, spasmodic manner, suddenly jumps up, and then makes expirations through the nose, rapidly following each other, the mouth being closed during each expiration, but making a kissing sound during each inspiration. The respiratory movements are at first very rapid, and subsequently become slower and shallower. The patient walks like an ataxic, and has been impotent for years. Vision, pupils, sensibility of skin, smell, taste, and muscular sense are all normal. Acuteness of hearing is slightly diminished. On both sides there is moderate galvanic hyperæsthesia of the auditory nerves, with paradoxical reaction. The case was regarded as a functional neurosis, induced by a reflex spasm in certain muscles of the thigh.

**A New Aural Retractor.**—Barth (*Arch. of Otol.*, xx, 1) describes a new retractor for separating the divided soft parts during the operation of chiseling into the mastoid process. It consists of two bars, each provided with three sharp-pointed hooks; these bars are connected by two rods and a screw in such manner that when approximated the hooks form a single line. After having divided the soft parts, including the periosteum, and having separated the latter from the bone, the hooks of the retractor are applied so that the points touch the bone at the spot where we wish to continue to operate. Then they are separated; the points of the hooks grasp the deeper soft parts, while the arms from which the hooks spring separate the more superficial soft parts and especially the divided integument, and push the auricle forward. When completely separated, the space included between the two arms presents a clear field for operation.

**The Route of Respired Air through the Nose.**—Kayser (*Arch. of Otol.*, xx, 1) asserts that during inspiration in the normal nose the bulk of the air passes along the septum, above the inferior turbinated bone, describing a semicircle in its course, and extending upward nearly to the roof of the nose. The general opinion that the current of air passes through the *pars respiratoria* is erroneous. The division of the cavity of the nose into a *pars respiratoria* and a *pars olfactoria* is permissible anatomically, but not justifiable physiologically.

**Bacteriological Examinations of the Contents of the Tympanic Cavity in Cadavers of New-born and Young Infants.**—Gradenigo and Penzo

(*Arch. of Otol.*, xx, 2) conclude from their investigations that the changes which are found very frequently in the tympanic cavity in new-born and young infants depend, in the majority of cases, upon the rapid decomposition which the delicate tissues of the middle ear undergo at this age, and not upon inflammatory processes, since no pathogenic microorganisms are found.

**Some Points concerning the Opening of the Mastoid Process.**—Heiman (*Arch. of Otol.*, xx, 2) sums up the indications for the operation as follows: 1. In acute purulent otitis media, complicated with inflammation of the mastoid process, when the inflammatory symptoms do not yield to antiphlogistic treatment and Wilde's incision. 2. In acute and chronic purulent otitis media, when the escape of the secretion is impeded by granulations in the middle ear or stenosis of the external auditory canal, or when there is a suspicion of inflammation of the mastoid process. 3. When the mastoid process is apparently healthy, but the removal of pus or cholesteatomatous masses through natural channels is impossible, and symptoms dangerous to life manifest themselves. 4. In congestive abscesses and fistulas in the region of the mastoid process. 5. In persistent, continuous pain in the mastoid process, yielding to no other treatment, especially when it seems sensitive to pressure. 6. As a prophylactic operation, in symptoms of retention of secretion and inflammation of the mastoid process, when death is to be feared on account of imperfect disinfection. 7. In acute purulent otitis media, in which there is no inflammation of the mastoid process, and no retention of secretion, but in which the discharge is very profuse, does not yield to the usual methods of treatment after a certain time, or even increases. 8. When there are distinct symptoms of inflammation of the brain and the meninges.

Heiman has used the trephine à *crémaillère* of Pasteur for opening the mastoid, and has received the following impressions from its use: 1. The removal of the compact portion of the mastoid process is much more rapid than with the mallet and chisel. 2. The edges of the wound need not be rendered smooth after the operation. 3. The different size of the trephines permits the formation of a wound in the bone of the desired size. 4. Shock is entirely obviated. 5. The depth of the wound can be graduated with exactness.

**Operation for the Relief of Deafness, Noises in the Head and Ears, and Vertigo, due to Chronic Catarrh of the Drum of the Ear.**—Sexton (*Arch. of Otol.*, xx, 2) reports seven such cases with results obtained from the operation suggested and practiced by him. He considers that in certain cases the advance of progressive sclerosis, and consequent deafness, tinnitus, etc., can not be arrested, nor, indeed, can any permanent improvement in hearing be made by means of any known local medication directed either to the ear itself or to the throat. The deafness due to progressive ankylosis of the ossicula may be arrested in most cases by an operation, however, and where the operation does not improve the hearing, the further increase of deafness is thus prevented. The operation, performed under narcosis, is not attended with any pain, and there is seldom any reaction or feeling of soreness in the ear afterward. Where there is a difference in the hearing power of the two ears, Sexton usually selects the worse ear for the operation, but this rule is by no means always to be observed. The operation itself is entirely devoid of danger. Antiseptic precautions are always to be taken. He does not always attempt to remove the incus, since it sometimes lies beyond the range of vision. As an immediate result of the operation, it will generally be found that the hearing for high tones has been improved sometimes very greatly. The ability to hear low tones is not always improved at first, but develops gradually. There is in some cases a consciousness of an entire change in the transmission of sound, which is confusing. More sound enters the ear, and it seems distant or crude. Sometimes tinnitus is increased for the first few days, but it gradually subsides. The drum of the ear requires no special after-removal of the drum-head, its lining soon being transformed from a mucous membrane to a dry, insensitive one, of a cicatricial or dermoid character. In some cases, after repair has taken place, an exfoliative process goes on for a short time in the drum or adjacent portion of the external auditory canal, giving rise to discomfort and even slight deafness, when the epithelial layer thus formed detaches itself. For a few hours after the operation the patients should remain in a recumbent position, and afterward confine themselves to the room for a day or two. Regeneration of the

drum-head can not be prevented from taking place in a certain number of cases, and when this occurs deafness returns, but the other symptoms, as a rule, do not return.

**A Contribution to the Histology of Aural Polypi.**—Klingel (*Arch. of Otol.*, xx, 2) reports an examination of fifteen cases of aural polypi. A purulent otitis was the cause of the polypi in all the cases. He considers that the majority of polypi are developed by chronic (more rarely acute) middle-ear suppuration, and primary inflammation of the external auditory meatus. The structure of the specimens showed three kinds of tissue: Myxo-fibroma, angelo-fibroma, and granulation tissue. The growth of aural polypi appears to take place in the separate lobules and particularly at the surface. The basal tissue is usually denser, poor in cells, and appears to cease to develop. Growth takes place chiefly in the recent, many-celled areolar tissue, in the granulation tissue, at the periphery of the tumors. The neighborhood of the vessels in the interior of the growth consists of granulation tissue, and it is by no means disproved that these are not the beginnings of vascular and other new formations. As regards retrograde changes, in addition to some hæmorrhages and pigment formation, there are small vitreous spots, which gave the impression of amyloid degeneration.

**Two Cases of Adenoma of the Sebaceous Glands of the External Ear.**—Klingel (*Arch. of Otol.*, xx, 3) reports two such cases, in which the tumors were of equal size, about as large as a pea, soft and sponge-like to the touch, with slightly roughened surface, and showing a few scattered hairs. The sections of these growths showed connective-tissue tumors covered with epidermis, in which there is seen a marked new formation of glandular elements, similar in character to normal glands. These growths should not be classed as papillomata, although the warty exterior, and the fact that they arise from the subepithelial connective tissue of the skin of the auricle, might suggest this view. But, in addition to the warty hypertrophy of the papillæ, there is a marked new formation of glandular elements. Hence these tumors should be called adenomata sebacea fibrosa.

**A Contribution to the Morphology of the Human Auricle.**—Gradenigo (*Arch. of Otol.*, xx, 3) calls attention to an anomaly occasionally met with in the human auricle, a minute stripe, which belongs to the set of longitudinal striæ, in the so-called triple division of the antihelix. This is represented by the third anomalous division starting from the locality of the usual bifurcation of the antihelix, or about the middle of the upper limb, and running backward and upward toward "Darwin's tip." The oblique striæ in transverse sections in the longitudinal axis of the auricle are less distinctly represented in man, but to this group belong the body and upper limb of the antihelix, and the lower limb of the antihelix. Gradenigo has also recognized the existence of two well-marked striæ, which must be regarded as accessory antihelices. One of these marks the elongation of the lower limb of the antihelix downward and forward, so that the stripe runs almost parallel with the antihelix itself, and terminates on the floor of the cymba conchæ directly over the erus helieis. The second very rare stripe is concentric with the body of the antihelix.

**Remarks on the Use of Styrene in Chronic Suppuration of the Middle Ear.**—Spalding (*Arch. of Otol.*, xx, 3) recommends the use of styrene, a compound of styrax and balsam of Peru, especially in cases of perforation of Shrapnell's membrane. It has a somewhat pleasant odor, which masks that of the most disagreeable discharges from the ear. It can be used, largely diluted with alcohol (one per cent. to five per cent.), to syringe out the meatus. It reduces the amount of the discharge and overcomes the latter's disagreeable odor.

**The Lesion in Deafness due to Mumps.**—Gellé (*Arch. internat. de laryngologie et d'otologie*, iv, 2) concludes from his observations that the infectious process, in the graver complications of the ear in parotitis, invades especially the nervous apparatus, and thus destroys the function of hearing. The delirium, vertigo, tinnitus, and absence of gross objective lesions seem to indicate the labyrinth as the seat of this destructive lesion. The atrophic sclerosis of the tympanic membrane and of the tympanum may also be the consequence of mumps.

**Two Cases of Carcinoma of the Auricle.**—Valyor (*Rev. de laryngologie et d'otologie*, Feb. 15, 1891) reports two cases of this rare disease. The first was a man, aged sixty-two, who ten years ago had noticed a moist, whitish, hard, wart-like mass, as large as a bean, near the in-

*cisura intertragica* of the left auricle. It was covered with a scab which he occasionally removed. Nine months before he presented himself the mass had begun to increase in size and to ulcerate, and eight months later he began to have severe pain in it. When Valyor saw him the whole auricle was thickened and increased in size, was indurated, and of a purple color. In the concha was a hard tumor, the size of a walnut, which extended upward to the *crus furcata inferior*, outward to the margin of the helix, and downward to the antitragus. The whole concha projected outward, was uneven, ulcerated, and bathed in pus, and was apparently divided by a broken margin, continuous with the auditory canal. Below the tumor was a flat, round, hard surface, as large as a walnut. The hearing was markedly diminished. An oval incision was made in the upper third of the helix, in a line with the center of the *fossa intercruralis*, as far as the outer margin of the concha; thence behind the auricle to the skin of the cranium, thence beneath the lobe of the ear to the incision made along the anterior plane of the concha. Having removed the latter, a curette was passed into the auditory canal, and all the carcinomatous masses were removed. The wound healed rapidly, and for eight months there has been no return of the growth.

The second case was a man, aged seventy, who for two months had noticed an increase in size of one of his ears. The auricle was purple in color, and looked as if it had been frozen, and was involved throughout its entire extent in a carcinomatous growth. All surgical interference was contra-indicated, on account of the great extent of the tumor, and the age and cachectic condition of the patient.

**An Electro-acoumeter.**—Cheval (*Rev. de laryngologie et d'otologie*, July 15, 1891) gives a description of an electrical acoumeter devised by himself, which consists simply of three spools or bobbins—the central one fixed, the other two movable in a slot or gutter. The electric current traverses the first spool or coil and reaches a commutator, which has three parts—an electro-diapason, a microphone, and an interrupter. Each of the induced coils may be attached to either of two telephones, which the patient keeps constantly in contact with his ears. The diapason and the microphone, when connected in the primary circuit, interrupt or modify its intensity, and consequently give rise to induced currents in the movable coils, which vary in intensity with the distance between the movable and stationary coils. The instrument permits (1) the operator to vary not only the intensity of the sound, but also the nature of this sound; (2) it allows of the verification of the patient's statements; (3) the course of the coils is more than 500 mm.; (4) the intensity of the sound is inversely to the square of the distance; (5) the hearing may be examined for any sound—for a musical note, for a combination of harmonic sounds, for the human speech, for the watch, or for the metronome.

**Deafness caused by Dry Inflammation of the Middle Ear and Ossicula, and the Surgical Treatment of the Same.**—Miot (*Rev. de laryngologie et d'otologie*, August 1 and 15, 1891) thinks that the extirpation of the tympanic membrane and extraction of a part of the ossicula, though a modern operation, has great advantages in certain cases, and he gives the following indications and contra-indications for performing the operation: The operation is indicated (1) whenever an artificial perforation sensibly ameliorates the hearing; (2) when the chain of bones and the drum-head have lost their motility; (3) when the patient has a paradoxical deafness, and hears the tuning-fork on the vertex best in the worse ear; (4) in cases of unilateral deafness, with vertigo and violent tinnitus. The operation is contra-indicated in cases of unilateral deafness without other objective symptoms, and in all cases where the tinnitus and deafness seem to be of nervous origin, reflex or central. He draws the following conclusions: This operation is the last resource to be employed in the treatment of dry catarrh of the ear. The removal of the drum-head and malleus may suffice whenever the membrane is much thickened and the motility of the bones is free. The malleus and incus must be removed in all cases of rigidity of the chain of bones. The result of the operation is generally very favorable, both as to tinnitus and deafness.

**A Case of Osteoma of the Cartilaginous Portion of the External Auditory Canal.**—Lichtenberg (*Rev. de laryngologie et d'otologie*, Oct. 1, 1891) reports a case of this kind occurring in a man, aged twenty-five, who had been very deaf for a year and had suffered great pain and

unbearable tinnitus in the left ear. There was a smooth, red tumor, completely filling the left auditory canal, eight millimetres long, and movable on its pedicle. It looked like a polypus, but there had never been any discharge from the ear. An exploration with the sound proved that it was attached to the internal wall. The case was removed easily by a snare without much hemorrhage. It was as hard as stone, and covered by a smooth, reddish capsule. An examination showed it was a neoplasm, containing a bony nucleus, surrounded by periosteum. It weighed eighteen centigrammes, was eight millimetres long, six millimetres wide, and five millimetres high. It proved to be an osteoma.

**Avulsion of the Stapes in Animals.**—Botey (*Ann. des mal. de l'oreille et du larynx*, xvii, 1), draws the following conclusions from his experiments: 1. The avulsion of the stapes in animals is an entirely innocuous operation. 2. Whether the oval and round membranes are torn or not, and whether labyrinthine fluid flows out or not, a new membrane, much thicker, is always formed after this operation. 3. In all cases, after removal of the stapes, the animals hear well, but at a shorter distance than before. 4. In animals which have neither drum-membrane nor columella, hearing is a little better than in those in whom the drum-membrane has been removed, while the stapes is left in place. 5. This operation would probably be equally innocuous in man, if it were possible to execute it equally well and under strict antiseptic precautions. 6. The drum-membrane and ossicula are not indispensable to hearing, but they simply re-enforce the intensity of sound-waves.

**A Theory of the Functions of the Sinuses of the Face, the Cells of the Ethmoid, and the Mastoid Apophysis.**—Coëtoux (*Ann. des mal. de l'oreille et du larynx*, xvii, 3) gives the following epitome of his views on the above subject: The ethmoid is primarily a respiratory and olfactory organ. The sinuses of the face share in this rôle, and later diminish its influence. Olfaction seems to owe its mechanism to the *alæ* of the nose and the vault of the palate. The ethmoid aids in the formation of the nasal fossæ, and preserves them from the deforming effects of aspiration in diffusing them. The moist and overheated air which it contains pushes the odoriferous particles toward the convexity of the middle turbinated bone. The sinuses, being developed with the olfactory sense, share with the ethmoid in its functions of diffusing the deforming effects of the negative pressure due to olfactory respiration. In the adult the sinuses leave to the ethmoid the first place. The mastoid cells relieve the tympanic membrane from the deforming effects of the barometric vacuum, which is due not so much to the olfactory respiration from which the narrowing of the Eustachian tube already protects it, as to the effects of this narrowing, which coincides with the development of olfactory respiration.

**Removal of a Revolver Bullet from the Temporal Bone by the Use of the Chisel; Recovery, with Preservation of Hearing.**—Wolf (*Arch. of Otol.*, xx, 3) reports the case of a girl, aged seventeen, who was shot by a revolver on October 15, 1889, the bullet entering the right ear. She fell, but did not lose consciousness, and was able to rise soon. There was but little hemorrhage from the ear and not much from the wound. Moderate facial paralysis developed on the eighth day, and there was a slight purulent discharge from the auditory canal. The bullet had entered just in front of the tragus, had crossed the external auditory canal obliquely, penetrated the posterior wall near the drum-membrane, and had lodged in the temporal bone. Wolf operated sixteen days after the injury. The auricle was detached posteriorly and pushed forward, the periosteum of the bony auditory canal was loosened, and the posterior wall of the canal was chiseled away in a backward direction. Constant oozing of blood from the bone interfered with the view of the bottom of the hole, and, as the porcelain-tipped probe did not locate the bullet, it was decided to postpone the completion of the operation for forty-eight hours. Two days later a good view of the depth of the hole was obtained and a small, shining, metallic point showed the position of the bullet. The bone was chiseled away around it, and after much difficulty it was removed by a pair of dressing forceps. An examination showed that the bullet had rested directly on the sinus. The auricle was reattached, the lower end of the wound being left open, and the subsequent course of the case was favorable. After three weeks, faradization of the facial was begun and caused a gradual improvement. The bony canal became pervious and the hearing distance became normal. During the operation no important parts con-

cerned in hearing were injured. The canal which was chiseled in the bone was located close behind the annulus tympanicus, so that the various parts of the tympanum and the semicircular canals remained intact. The facial nerve seems merely to have been compressed and not torn by the bullet. The occurrence of facial palsy only after several days was due to a neuritis from pressure, and when this subsided the nerve became again capable of conduction.

**The Use of Electricity in Chronic Affections of the Middle Ear.**—Baxter (*Arch. of Otol.*, xx, 3) reports ten cases of disease of the middle ear treated by the constant current. He thinks that when improvement takes place it is most noticeable in the increased ability to understand speech, the tinnitus is lessened, the feelings of pressure, fullness, and dullness are lessened or removed. The method of application is as follows: After placing the patient with the head inclined the external auditory canal is filled with warm water, the aural electrode (a small wire insulated to within two millimetres of its point) is introduced into the auditory canal and retained there by the fingers of one hand, leaving the other hand free to manipulate the switch, rheostat, and pole-changer; the other electrode, covered by a sponge, is held in the patient's hand. The current is then switched on and gradually increased, watching the milliampèremeter until from five to ten milliampères of current are passing through the parts; then, retaining the electrodes in position, the poles are changed two or three times a minute. From three to six minutes suffice for an application. The ear is then dried and the patient kept quiet for a short time to recover from any possible vertigo.

**The Symptomatic Value of the Pulsations noticed in the Ear by the Endoscope.**—Gellé (*Ann. des mal. de l'oreille et du larynx*, xvii, 9) draws the following conclusions from his observations: By the aid of the endoscope the state of the circulation of the blood in the tympanic cavity can be studied; in active congestion of the tympanic mucous membrane this instrument shows pulsations isochronous with the pulse. This demonstration is especially useful when the objective symptoms are wanting. The pulsations of the endoscope actually show the activity of the inflammatory process in the middle ear. They disappear when the process declines, but persist as long as the abnormal vascularity lasts. Hence they have an important prognostic value in chronic diseases. Their absence in certain cases of subjective affections of congestive appearance enables us to localize the seat of the exudation in the deeper parts of the organ, or to recognize the purely nervous origin of the phenomena.

**Diagnosis, Prognosis, and Treatment of Progressive Deafness due to Chronic, Non-purulent Otitis Media.**—Gradenigo (*Ann. des mal. de l'oreille et du larynx*, xvi, 12) summarizes as follows: Chronic catarrhal otitis media is generally characterized by a slowly progressive morbid process, which is usually located in the middle ear, but which often extends to the internal ear, and causes more or less complete deafness. As regards the prognosis, two principal circumstances are to be considered: 1. The existence or absence of functional lesions attributable to the internal ear, in addition to functional lesions located in the transmitting apparatus. 2. The existence or absence of retraction of the drum-head.

Some cases are distinguished by the predominance of morbid phenomena, which must be referred to the drum-head and Eustachian tube—such as redness and retraction of the membrane. In other cases the lesions are generally located in the vestibular wall—such as ankylosis of the stapedo-vestibular joint. In still other cases the lesions of the internal ear predominate.

Gradenigo considers the subject of treatment under five heads, as follows: I. Direct treatment of the ear: 1, through the external auditory canal, by massage of the ossicles, by massage of the tympanic membrane, and by intratympanic surgery; 2, through the Eustachian tube by catheterism with a simple air-douche, by injection of medicated vapors through the catheter into the drum, by injection of liquids through the catheter into the drum, or by the methodical introduction of bougies and massage of the Eustachian tube. II. Local treatment of the nose. III. General constitutional treatment. IV. Treatment by the electric current.

**Cholesteatoma of the Ear.**—Kuhn (*Arch. of Otol.*, xx, 4) reports a case of "true cholesteatoma"—that is, a tumor which originated pri-

marily in the mastoid process, and which had during many months, and perhaps years, grown to its tremendous dimensions. The symptoms which appeared during the last year (tinnitus, dizziness, and deafness) were due to erosion of the external portions of the ear, and to pressure on the cerebellum. Exposure toward the end caused the acute symptoms of inflammation and disintegration of the tumor, which had then extended to the posterior wall of the auditory canal. The presence of a membrane lining the bony cavity is not proof of the primary origin of the tumor, for it may have been due to the pressure of the tumor on the periosteum and bone. Cholesteatoma of the temporal bone is either a true heteroplasmic neoplasm, or it may develop in the course of chronic suppuration of the middle ear, from epidermis which had grown into the tympanic spaces from the perforated drum or external auditory canal, which has slowly and continually shed its horny layer, thus forming the stratified cholesteatomatous mass.

**The Treatment of Cholesteatoma of the Middle Ear.**—Bezold (*Arch. of Otol.*, xx, 4) thinks that if in these cases the cavity is rendered free by a large opening into the wall of the canal or of the mastoid process, suppuration ceases, and so also does the hyperproduction of epidermis. More than half the cases are complicated by polypoid granulations, usually exposed by pressure from the cholesteatomatous masses which act as foreign bodies. Only a portion of the granulations is found in the canal, the greater part being at the margin of the perforation. On this account it is frequently impossible to remove all the granulations with the snare. The operation of excision of the malleus and incus is an aid in the treatment. It seems absolutely necessary to use Hartmann's or some other tympanic syringe in all cases, not only therapeutically, but also for the purpose of diagnosing the existence of cholesteatomatous masses. Bezold uses an injection of a four-per-cent. solution of boric acid. When preliminary softening seems necessary, diluted liquor ammoniac may be used. When the size of the cavity admits, he uses a sharply bent tympanic tube of large cavity, for direct insufflation of boric acid.

**A Case of Deaf-mutism caused by Measles, with Post-mortem Examination.**—Mygind (*Arch. of Otol.*, xx, 4) reports a case of this sort occurring in a man aged twenty-eight. At the age of eighteen months the patient contracted measles, and during the attack a bilateral inflammation of the middle ear set in, probably secondary to an acute catarrh of the naso-pharynx. The former existence of such an inflammation was proved by the inflammatory residua found at the autopsy, viz.: 1. On the external wall the left membrana tympani almost entirely wanting, while the right one was the seat of a large calcareous deposit, and there was a bilateral purulent discharge. 2. On the posterior wall of the tympanum the aditus ad antrum mastoideum was closed and the mastoid process was sclerosed. 3. The internal wall of the tympanum was the seat of stalactitic formations which exhibited strong evidence of a severe inflammation of the osseous structure of the tympanum. 4. The normal muscles of the tympanic cavity were missing on either side. The inflammation was propagated from the middle ear into the labyrinth through the fenestra rotunda, destroyed the cochlea, and in its place produced sclerosed osseous tissue.

**A Case of Partial Development of both Auditory Organs.**—Heiman (*Arch. of Otol.*, xx, 4) describes an interesting case in a child two days old. There was complete absence of both external meatus, with an incomplete development of the auricles. The posterior part of the palate was absent, the articulation of the temporal bone with the zygoma was incomplete, and the middle ear undeveloped. The skin and cartilage of both ears were well developed. The lobules and helices were normal. The upper border of the left helix is adherent to the facial skin. The antihelix and crura bifurcata are replaced by a cartilaginous, ring-like tuberosity, whose convexity is directed inward. There is a distinct depression in this circular piece of cartilage. The site of the external opening of the meatus on both sides is marked by a slight furrow. On the right side, in front and above this furrow, are two cartilaginous tubercles covered with normal skin. The cartilage of the tragus could be plainly felt. The nasal structure was normal.

**A New Universal Double-acting Snare.**—Bucklin (*Arch. of Otol.*, xx, 4) has devised an instrument in which the wire is attached to a solid stylet, drawn by a powerful ratchet motion. A screw motion is also attached to the same stylet, thus enabling the operator to use a very slow-

cutting snare, while the ratchet motion provides a rapid-cutting one when desired. The handle and ratchet motion may be detached at pleasure. The instrument has a straight tip for the nose and curved tips for reaching the larynx and naso-pharynx through the pharynx. The straight cannula is armed with wire by passing it through the eyes of the slightly projecting stylet from opposite sides. The required loop having been formed, the stylet is drawn by the ratchet motion, and the projecting ends of the wire are cut. The curved tips are armed with wire by bending one sixteenth of an inch of the end of the wire at an angle of forty-five degrees. It is then passed through the first eye of the stylet into the opening at the curve of the cannula. When the wire appears at the opening it is twisted until the bent point is opposite the second eye in the stylet, which it enters easily and the loop is complete.

**Different Diagnostic Points between Human Olfactory Epithelium and Respiratory Ciliated Epithelium.**—Suchanek (*Arch. of Otol.*, xx, 4) considers that the normal human olfactory epithelium consists: 1. Of a living membrane of finest ciliated epithelium of easily differentiated, easily destroyed cilia, and therefore only to be seen in fresh specimens. 2. A protoplasmic border of unpigmented and pigmented cells containing the extreme terminations of the supporting and olfactory cells. 3. A full development of supporting cells, and particularly of the zone of olfactory cells, together with a row of basal cells, which, without a dividing cuticle, rest directly upon the tunica propria. 4. A moderate amount of pigment which surrounds Bowman's glands and the olfactory fibers in heaps and stripes.

**Aural Complications in the Course of Leucocythæmia.**—Lanouis (*Ann. des mal. de l'oreille et du larynx*, January, 1892) draws the following conclusions from his observations: 1. Leucocythæmia may be accompanied by symptoms of the presence of lesions in the auditory apparatus. 2. These symptoms are either unilateral or bilateral deafness, accompanied or not by subjective noises and vertigo. 3. This variability of symptoms depends upon the fact that the lesion does not always involve the same region in the auditory apparatus. 4. In four cases out of five the anatomical lesion is a hæmorrhage. 5. These complications are relatively rare.

**Malignant Tumors of the Ear.**—Charazac (*Rev. de laryngologie et d'otologie*, Jan. 1, 1892) refers to the fact that all the cases hitherto reported seem to prove that cancers of the auricle and external auditory canal are the most frequent of all malignant diseases. Epithelioma is the most frequent form of cancer of the ear, and sarcoma is the next most common. Carcinoma is the least common form of malignant disease of the ear. We meet here with both forms of epithelioma—the cylindrical and squamous—the latter being both tubular and lobulated.

Malignant tumors of the ear are met with at all ages, though epithelioma and carcinoma are most frequently met with in declining years, while sarcoma is more frequent in the young. Cancer of the auricle is not more frequently met with in women than in men, though it might be expected to occur oftener in the former, because of the piercing of the lobules for ear-rings. Epithelioma is much more frequently met with in men than in women.

Cancer of the ear may develop primarily in all parts of the auditory apparatus—even in the middle ear and mastoid cells. Epithelioma of the auricle and auditory canal sometimes occurs as the result of traumatism. In many cases it is developed in the course of cutaneous diseases, like eczema, impetigo, and psoriasis. According to Politzer, epithelioma of the auricle appears most frequently on the skin of the upper part of the helix. Sarcoma most often attacks the lobule. In the auditory canal the cartilaginous portion is the most frequently affected.

Whatever the variety of cancer, when the parts have become ulcerated the pain is often intense, radiating from the interior of the ear to the corresponding side of the head. The engorgement of the pre-auricular glands occurs sooner or later, presenting itself very late in the case of sarcoma. When ulceration has occurred, the growth is usually very rapid. Carcinoma, as a rule, grows very rapidly. As regards prognosis, sarcoma is less grave than epithelioma, and the latter less grave than carcinoma.

Cancer of the middle ear may be primary or secondary. The latter arises very often from a neoplasm of the auricle or canal. The prog-

uosis is absolutely fatal, for it is impossible to extirpate the neoplasm totally. The treatment should, therefore, be merely palliative.

Primary cancer of the labyrinth, if it exists, is excessively rare. It is almost always secondary, epithelioma and carcinoma being the most frequent, if derived from the middle or external ear, while sarcoma derived from the intracranial cavity is the most frequent.

## Miscellany.

**The Legal Requirements for entering upon the Practice of Medicine in the State of New York.**—The following report has been prepared under the auspices of our State board of medical examiners, which, in brief, outlines the law of the State and its operation since September 1, 1891. It has been prepared more particularly with a view to disseminating knowledge on a subject concerning which frequent inquiries are made, and it is thought that the profession will be pleased to have the opportunity of reading a concise statement of the essentials for entering on the practice of medicine in the State of New York, and of knowing the result of a nine months' trial of the latest legislation.

The report is as follows :

The many inquiries directed to the regents' office and to the secretaries of the various State boards of medical examiners indicate that the profession is largely interested in the operations of the law at present governing the practice of medicine in the State of New York. This interest is accepted as of sufficient moment to warrant the publication of the salient features of the law, and at the same time to give the profession an insight into the methods and machinery necessary to its proper enforcement. The law signed by the Governor on June 4, 1890, went into effect on September 1, 1891, and has been operative since that time. It provides: "From and after the first day of September, 1891, any person not theretofore lawfully authorized to practice medicine and surgery in this State and desiring to enter upon such practice" may, after the following conditions have been fulfilled, receive an order to be examined before one of the three State boards of medical examiners as to his medical qualifications :

1. Applicant must be more than twenty-one years of age.
2. Must present certificate of moral character from two legalized resident (State) medical practitioners.
3. Must be a graduated doctor of medicine from some legally incorporated medical college in the United States, or have received a diploma or license conferring the full right to practice all the branches of medicine or surgery in some foreign country.
4. Must have attended at least three full courses of lectures in different years in some legally incorporated *medical* college or colleges.
5. Must pay twenty-five dollars into the treasury of the University of the State of New York.
6. Must present evidence of preliminary education, as follows :  
Either—  
(a) Usual academic degree.  
(b) One year at academic degree-conferring college.  
(c) Three years in a high school or academy.  
(d) Be in possession of regents' medical-student certificate.  
(e) Matriculation certificate required by present medical act of Canada.  
(f) Matriculation certificate from any university in Great Britain or Ireland.  
(g) Certificate of having passed examinations of any registered institution equivalent to one year in academic college or three years in high school.

All these preliminaries having been complied with, upon proof presented by the applicant, in his or her own handwriting, to the satisfaction of the regents (on blank forms furnished on application), an order is given admitting the candidate to the next examination. Five regular examinations are held during the year (during the year 1892 there are still three regular examinations to be held, as follows : June 14th–17th,

September 27th–30th, and November 22d–25th) simultaneously at New York city (21 Cooper Union), Albany High School building, Syracuse High School building, and Buffalo High School building, and as many special examinations are ordered as are deemed necessary by the regents, depending upon the exigencies which may arise. At these examinations the candidates are examined on the subjects of (1) anatomy, (2) physiology and hygiene, (3) chemistry, (4) surgery, (5) obstetrics, (6) pathology and diagnosis, and (7) therapeutics, including practice and materia medica. The candidate is allowed three hours' time in which to answer ten from among the fifteen questions submitted on each topic; each answer, if correct, has a value of ten points, and *each* full paper of ten questions answered must have a total value in markings of at least seventy-five points; otherwise the candidate is rejected. There are two sessions of three hours daily, each session devoted to one of the seven topics; thus three days and a half are requisite for completing the examination. The candidates are examined according to number, no name being allowed to appear on the answer papers; the name of the candidate is placed in an envelope marked with the corresponding number, is sealed, and left unopened until the final report of the examiners has been made.

There are three boards of State medical examiners as follows, representing the—

*Medical Society of the State of New York.*—William C. Wey, M. D., president, physiology and hygiene; Maurice J. Lewi, M. D., 71 Lancaster Street, Albany, secretary, chemistry and materia medica; William S. Ely, M. D., anatomy; George Ryerson Fowler, M. D., surgery; William Warren Potter, M. D., obstetrics; J. P. Creveling, M. D., pathology and diagnosis; Eugene Beach, M. D., theory and practice and therapeutics.

*Homœopathic Medical Society of the State of New York.*—Asa S. Couch, M. D., president, pathology and diagnosis; Horace M. Paine, M. D., 105 State Street, Albany, secretary, anatomy; A. R. Wright, M. D., physiology and hygiene; John McE. Wetmore, M. D., chemistry; E. E. Snyder, M. D., surgery; William S. Searle, M. D., obstetrics; Jay W. Sheldon, M. D., therapeutics, practice, and materia medica.

*Eclectic Medical Society of the State of New York.*—Hugh J. Linn, M. D., president, obstetrics; Edwin S. Moore, M. D., Bay Shore, secretary, surgery; William L. Tuttle, M. D., anatomy; Robert Hamilton, M. D., physiology and hygiene; Harry B. Smith, M. D., chemistry; John P. Nolan, M. D., pathology and diagnosis; John H. Dye, M. D., therapeutics, practice, and materia medica.

They are appointed by the regents from nominations submitted by the State, Homœopathic, and Eclectic Medical Societies, for a term of three years, for every vacancy two names being submitted by the societies. The principal work of the examiners is to formulate questions for examination purposes and to mark the answers thereto. The questions submitted at each examination are the same for all candidates, excepting on the seventh topic (therapeutics, practice, and materia medica), three sets of questions being furnished at each examination, each set representing the views of one of the three legally incorporated schools of medicine in the State on this subject, the candidate receiving the set for which he had expressed a wish in his original application for license. The questions to be used at the various examinations are decided upon as follows, those previously secured in a similar way having become exhausted: The regents issue a notice requesting each of the twenty-one examiners to forward, on or before a certain date, sixty questions on the special topic to which each is assigned; subsequent to this date the questions board, consisting of six members, two from each board, is called in session. The questions on the seventh topic are handed to the two members representing their special board, who, as previously stated, and as particularly specified in the law, have complete charge of this subject. With the other six subjects, one hundred and eighty questions having been submitted in each, the questions board acts as follows, taking anatomy, for instance: The secretary reads a question alternately from each of the three papers submitted by the examiners in this topic, and, unless each receives the unanimous vote of all present, it is stricken from the list of available questions. The one hundred and eighty questions, having passed through this process, are arranged in sets of fifteen, each set is numbered and sealed, and thus at one sitting, lasting, however, many hours, an average of ten complete sets of questions is pre-

pared, thus providing for ten future examinations. These sets of questions are placed in the custody of the regents, who, as the time for the next examination approaches, call upon the secretary of the questions board to review the printer's work after the questions are put up in type. The examinations proper are conducted by a sworn official of the regents' office, who is not a member of any one of the State boards of medical examiners. As soon as the examinations are concluded the answer papers are delivered to the secretary of the board selected by the candidate in his application, and by him in turn sent to the different individual examiners, who return the papers with their markings to the board of regents; these answer papers thereupon become a part of the public records of the State. If a favorable report is made by all of the examiners on the answers of any applicant, a license is immediately forwarded to his address, thus enabling him to register at once and commence the practice of his profession. The last examination was concluded on May 6th, and on May 14th the licenses were forwarded from the regents' office to the successful candidates. Arrangements are now being made for the next examination which will enable the regents to forward these licenses within five days of the close of the examinations. The income accruing from this law goes to the Board of Regents, who, after paying all proper expenses, will, if ever there should be a surplus, apportion the money among the twenty-one examiners according to the number of candidates examined by each. Graduates in medicine who have been licensed by State examining boards of other States of the United States only, on convincing the Board of Regents that the standard of requirements adopted by the board of examiners which granted them the license is substantially the same as in New York State, may, upon the payment of \$10, have such license indorsed. The following summary of the laws has been made:

1. The University of the State of New York is the only organization having authority to issue licenses to practice medicine in this State after September 1, 1891.

These licenses must be registered by county clerks on application. (*Laws of New York*, 1890, ch. 507, § 8-9.)

2. Licenses issued before September 1, 1891, can be registered only as follows:

(a) A diploma granting the degree M. D. issued before September 1, 1891, by an incorporated medical college in this State is a license to practice medicine and must be registered on application. (*Laws of New York*, 1889, ch. 647, § 2.)

(b) A diploma granting the degree M. D. from a medical college out of the State, or a license to practice medicine in some foreign country, can be registered only if it was indorsed between June 18, 1880, and June 24, 1890, by an incorporated medical college of the State of New York or by the University of the State of New York, or, if between June 24, 1890, and September 1, 1891, it was indorsed by the University of the State of New York. (*Laws of New York*, 1880, ch. 513, § 4; 1887, ch. 647, § 2; 1890, ch. 500.)

3. Students who had matriculated in a New York State medical college prior to June 5, 1890, and had not received the degree M. D. prior to September 1, 1891, to be exempt, must have filed a certificate with the University of the State of New York before August 4, 1891. (*Laws of New York*, 1891, ch. 311.)

Licenses of such candidates may be registered as follows:

(a) A diploma granting the degree M. D. from a New York State medical college issued after September 1, 1891, can be registered on presentation of a certificate from the secretary of the University of the State of New York that the applicant had matriculated in some medical college of the State prior to June 5, 1890. (*Laws of New York*, 1891, ch. 311.)

(b) A diploma granting the degree M. D. from a medical college not in the State or license to practice in a foreign country, if indorsed by the University of the State of New York, can be registered on presentation of a certified copy of a certificate filed with the secretary of the University of the State of New York that the applicant had matriculated in some medical college of the State prior to June 5, 1890. (*Laws of New York*, 1891, ch. 311.)

All diplomas issued by medical colleges in this State prior to January 1, 1880, which are presented for registration after this date should be referred to the University of the State of New York for examination

before being registered, and further, to quote the exact wording of the law:

SECTION 10. Nothing in this act shall be construed to interfere with or punish commissioned medical officers serving in the army or navy of the United States or in the United States marine-hospital service while so commissioned, or any one while actually serving as a member of the resident medical staff of any legally incorporated hospital, or any legally qualified and registered dentist exclusively engaged in practicing the art of dentistry, or interfere with manufacturers of artificial eyes, limbs, or orthopaedical instruments or trusses of any kind from fitting such instruments on persons in need thereof; or any lawfully qualified physicians and surgeons residing in other States or countries, meeting registered physicians and surgeons of this State in consultation, or any physician or surgeon residing on the border of a neighboring State, and duly authorized under the laws thereof to practice medicine or surgery therein, whose practice extends into the limits of this State; providing that such practitioners shall not open an office or appoint a place to meet patients or receive calls within the limits of the State of New York; or physicians duly registered in one county of this State, called to attend isolated cases in another county, but not residing or habitually practicing therein.

Appended will be found the examination results thus far obtained:

Total number of applicants for license to practice medicine to date .....	56
Number of those who fulfilled all requirements and received license.....	34
Number of applications still unacted upon.....	10
Rejected for failure to reach seventy-five per cent. at final medical examination.....	1
Deficient in preliminary education.....	6
Had never attended three full courses of lectures....	4
License withheld because of moral reasons.....	1
	56

*Addenda.*

All examinations are conducted in English unless the applicant expresses a desire to be examined in *Latin*. In that event the application, with the reasons therefor, is placed before a committee consisting of the presidents of the three boards, whose decision is accepted by the board of regents. The candidate must pay the expenses of translation. Whenever it is found necessary to obtain the opinion of the boards of examiners, the university authorities are requested to confer with a sub-committee of the conference consisting of the president and secretary of each board, who are the executive committee of the boards. The boards proper meet twice in each year.

A syllabus is in course of preparation and will be issued shortly. A candidate having failed, whether in one or all seven branches, his application for license is rejected. On re-examination no fee is exacted, but the candidate must pass the examinations on all seven topics, regardless of the number he passed at the previous examination. Appeal for a reopening of any examinations may be made to the regents of the University.

Indicating point to a class of from fifteen to twenty applicants at the next regular examination, June 14, 1892.

By order of the State board of medical examiners representing the Medical Society of the State of New York.

MAURICE J. LEWIS, *Secretary.*      WILLIAM C. WEY, *President.*

**District Nursing in Germany.**—The following letter from an occasional correspondent of the *British Medical Journal* was published in that journal for May 21st:

Supposing a working man or a member of a family with limited means, but not exactly paupers, were to fall ill, who would look after and nurse the patient if his own people were not in a position to do so, and if the case was not taken to a hospital? In answer to this question, I am happy to be able to point to a pretty considerable number of extensive and well-organized institutions in the German Empire, all devoted more or less exclusively to this duty.

Foremost among these, at least in the Protestant parts of the Fatherland, stand the highly esteemed and meritorious Deaconesses' Homes

(Diakonissen Anstalten). The first institution of this kind was founded in the very humblest fashion, and under great difficulties and privations, by the late Theodor Friedner, in Kaiserwerth, on the Rhine, in the year 1836. From lowly beginnings, however, his work has spread all over Germany, and even beyond the limits of Europe. At present most of the chief towns of the empire (Berlin, Hamburg, Dresden, Karlsruhe, Darmstadt), in all about sixty, contain similar independent centers of organization in conjunction with a hospital (Mutterhäuser), from which the sisters are sent out to yield the aid required in the respective provinces. The number of deaconesses at work in Germany in 1888, exclusive of those engaged in foreign parts, amounted in round numbers to 5,000, and is still steadily increasing. Their duties extend a good deal beyond district nursing. They apply themselves, if so qualified, to teaching, to taking care of little children in crèches (Krippen), etc. The institution of the last seems to be a very useful complement to the work of district nursing, the children informing the sisters of cases of sickness in the family, and, on the other hand, the parents showing much more inclination to send their children to the preliminary school after having made the acquaintance of the deaconesses in illness and distress.

The working of all these homes appears to be pretty much the same everywhere. Reputable females of all stations, not younger than eighteen and not older than forty years of age, are always admissible to become members. They are required, first of all, to pass a few weeks on preliminary trial; if found fitted, both mentally and bodily, for the duties of the order, they are received as probationers, and are further trained for two years or more as may be judged appropriate in each individual case. Much weight is given to the religious part of the training, but the practical portion of the education in nursing, as far as my experience in a number of hospitals goes, is most efficient and thorough. On entering, a novice is required to bring with her nothing but a limited supply of clothing, her Bible, hymn-book, and prayer-book, and a very little ready money in case of need. If received as a probationer (Probeschwester), she is supplied with the dress of the order, and receives a small monthly allowance. The number of those who quit the service, unless compelled to retire from failing health, is very small. Occasionally a deaconess will resign in order to marry, or on account of her own people being in need of her aid, but this does not happen very often.

Although their expenses are comparatively inconsiderable, almost all these houses are continually in want of pecuniary aid, and their sphere of work might be vastly extended. Unnecessary outlay is carefully avoided. Their income is derived chiefly from voluntary contributions, their capital not being very extensive, and the income gained by services rendered being proportionately very small, as most of the work is done entirely gratuitously. In some places the congregation of the district makes arrangements with the Deaconesses's Home, and engages one of the sisters to act as nurse of the district (Gemeindepflegerin) by the year, for which the home receives a small remuneration. In other towns, again, there are so-called Krankenvereine—sickness associations—of which the members pay regularly a small subscription toward the funds of the home, which entitles them to free nursing in case of need. As a rule, however, the sisters thus subsidized are engaged in attending the poor of the district, so much so that the money received is far more than fairly earned by the work done.

At some of the homes—for instance, at Wehlheiden-Cassel—arrangements are now made for the purpose of supplying small towns and villages with trained nurses in the same manner as the state provides them with trained (and registered) midwives. Any respectable female, between twenty and forty years of age, chosen by the authorities or by associations willing to pay the necessary twenty shillings a month to the home, can be received as a pupil under the same conditions as the probationers, and having received six months' education in nursing, and having passed an examination, can return home and begin work as a certified nurse. Similar dispositions have been made by some of the Frauenvereine—for instance, in Karlsruhe. In this way even small villages will be possessed of at least one inhabitant with some idea of the necessities of a sick-bed and capable of yielding help to the destitute during illness.

A new extension of the deaconesses's work in Berlin was recently

set on foot at the instigation of the Empress, and promises to prove of great value. It consists in the formation of an extensive series of deaconesses's stations distributed throughout the laborers' quarters, each station to contain five sisters, whose sole duty it is to attend to the sick poor in their own homes. All the mother houses have been called upon to depute a number of members for the work; here there is certainly a wide field of labor, the homes already in activity there, with thirty sisters engaged especially in district nursing, not being at all sufficient to meet all the demands. It may be as well to mention that the homes are often called by different names in the different towns. Thus, in Berlin there are four houses—the Elizabeth Hospital, Bethania, Lazarus Hospital, and the Paul Gerhardtstift, all conducted independently of each other by deaconesses. In Hamburg the home is also called "Bethania"; in Wielefeld, "Sarepta"; in Hanover, "Henriettenstift"; in Darmstadt, "Elizabethhaus," etc. At the head of each home is a committee composed of influential and well-known—sometimes royal—persons, while the daily care for the institute devolves on the matron (or Oberin). The homes just mentioned are all in connection with a hospital, except the Paul Gerhardtstift, which serves chiefly as a place of abode for elderly females who are without families. Besides the deaconesses, we have also deacons, as at the fraternity house, Nazareth, near Wielefeld, and at Karlshöhe, near Ludwigsburg, in Württemberg; but their sphere of action extends only quite exceptionally to district nursing.

Very extensive and useful institutions are the Associations of the Red Cross, the Prussian Vaterländischer Frauenverein, which is extended to some of the non-Prussian German states, then the Bayerischer Frauenverein in Bavaria, the Badischer Frauenverein in Baden, the Alice Verein in Hesse-Darmstadt, the Marien Frauenverein in Mecklenburg, the Albert Verein in Saxony, the Wohlthätigkeitsverein in Württemberg, and the Frauenverein in Saxe-Weimar-Eisenach. These seven corporations constitute together the Verband der deutschen Frauenvereine, the Conjoint Woman's Association of Germany, but each is conducted and organized quite independently of the others. They are under the patronage of the Landesmutter—that is, the consort of the reigning sovereign of the land, and all persons willing to take part in the work of the association are readily admitted on payment of an annual subscription of six shillings. In consequence, the number of the members is very large, and they command a very fair annual income. In conjunction with the Männer Hilfsvereine, Men's Aid Association, their prime object is to supply the necessary means of nursing the sick and wounded in case of war; but, besides this, they aim at affording relief of all kinds to the needy both in case of unusual calamities (floods, fire, famine, etc.), and also in the usual course of things. These associations are in possession of a large number of hospitals throughout the land, where nurses are educated both for voluntary and for paid service. The course of instruction is arranged and conducted in about the same way as with the deaconesses, and comprises periods of novitiate, probation, and qualification. They, too, have a uniform kind of dress for the sisters, who are especially distinguished by the brooch bearing a red cross on a white field. The pecuniary remuneration is a little higher than that of the deaconesses, and, owing perhaps to this circumstance and to the patronage of royalty, many ladies are to be found among the sisters. Their labor is chiefly, indeed, directed to hospital nursing, but district nursing is also largely attended to. In the latter direction, too, a great deal of good is done in all the branches by supplying the indigent sick with the necessities of life, and often, also, by procuring the necessary funds to sustain a deaconess for the respective congregations. The Frauenvereine comprises both Protestant and Roman Catholic members. Of the Roman Catholic religious orders a very considerable number are engaged in nursing, both in hospitals and in the district, and they are universally most highly esteemed on account of their eminent qualities in this respect. They are extremely reticent with regard to their organization, and a few have, on inquiry, declined to give further information. I am, therefore, unable to mention details with regard to them. Suffice it to say that, as in the purely ecclesiastical monasterial orders, a novitiate has to be passed, and that for their training, in consequence of the numerous hospitals in which these orders are engaged in nursing, ample opportunities exist. Among the most extensive orders may be

mentioned the Sisters of Mercy of the Order of Karl Borromaeus, with their center in Trebnitz (Silesia); the Gray Sisters of the Labor of St. Elizabeth, originally of Neisse and Breslau, and extended through a very great part of Germany. Further, we have the Handmaidens of Christ, of whom about 800 are engaged in district nursing here. Their center is in Dernbach (Nassovia). The Sisters of the Congregation of the Very Holy Saint Saviour (Niederbronn, in Alsatia) number about 1,400, including novices, and are for the greater part solely engaged in nursing the sick poor. There are also the Sisters of St. Clement (Aix-la-Chapelle), of St. Celestine (Cologne), of St. Francis, in Gengenbach (Baden), and elsewhere; of St. Vincent de Paul, founded in Metz in 1633, and widely distributed also in Protestant parts—districts, for example, in Württemberg. In some places associations have been formed among the laity (for instance, in Karlsruhe, in combination with the Sisters of St. Francis in the St. Bernhard House), the members paying a small annual subscription toward the expenses of the order, and receiving in case of need gratuitous nursing in the same way as has been described with regard to the Protestant deaconesses. As a rule, no sisters of the Catholic orders are permitted to attend in cases of midwifery unless a fortnight has elapsed since the birth of the child. An exception to this law are the *Sœurs de la Charité Maternelle*, established in Metz, who make it their chief duty to attend poor mothers in child-bed, and to supply them with the necessary help, and also, if need be, with nourishment, medicine, and articles of clothing. Among the monks, some of the Franciscans (Capucins) in various cities also devote themselves to nursing; likewise the Brothers of Mercy in Werne, Montabaur, Straubing, Treves, Breslau, and other places; and the Brothers of St. Alexis (Münster, etc.), but their number is comparatively limited. In general, it would appear that the number of institutions, both Catholic and Protestant, founded for the purpose of helping and nursing the sick poor, is large enough, but by almost all the same lament is made—that they are unable to cope with the ever-increasing demands made on them both for want of funds and of active members.

**III. The Ideal Consultant.**—When, says the *Lancet*, nearly a generation ago, Sir Henry Acland in a memorable publication introduced the Oxford Museum to the academic world and foreshadowed the benefits it would bring to liberal culture as a whole, and more particularly to that of the physician, he gave a picture of the "ideal consultant" which, if more comprehensive than detailed, may be said to come as near perfection as such compendious characterizations are capable of reaching. In a quotation from Suidas he adduced the answer of the consultant Trophilus, when asked to define the all-accomplished physician: "It is he," said Trophilus, "who is able to distinguish between what can and what cannot be done." This definition may be said to cover every requisite in the medical adviser in whatever circumstances the exigences of his calling may place him; but it does not, of course, enter into native aptitudes, or acquired dexterities, or, in short, into the *ensemble* of qualifications which combine in the physician who is ever ready and never at fault. One definition, or rather indication, of what the successful consultant really is was incidentally given some years ago, by an outsider, in a strictly professional controversy—a definition which embodies the lay belief in the personal power of the physician apart from what special discipline can make him. "A great physician," he said, "is a great artist." This also is true, and will be found on closer analysis to explain the extraordinary success of practitioners whose book-learning or laboratory training is notoriously far inferior to their power in diagnosis and their success in treatment. The Athenian intellect at its best and in its most characteristic mood—essentially artistic as it was—seemed to fulfill the requisites which from time to time attain medical embodiment in a Sydenham, or, to come within our own day, in a Bamberger, whom, *consensu omnium*, each morning's encounter with cases of every kind in the Vienna wards found seldom or never at a disadvantage. That intellect, in its combination of nimbleness with strength, of centripetal insight with sense of proportion and judicial balance, has been described for all time by Thucydides in his wonderful picture of Themistocles. He dwells on the native understanding of "that Athenian of Athenians"; on his power, without previous information or after-thought, with, indeed, the briefest consideration of the problem in hand, to form a picture in his mind of what it really implied and of what its solution

would yield—diagnosis, in short, and prognosis, almost improvised as to readiness; and again, when the problem admitted of only an approximate or provisional solution he could—"this way and that dividing the swift mind"—alight on the better and avoid the worse interpretation, even in the absence of previous prompting or of the data indispensable for less artistic minds. The whole passage (*Thuc.*, i, 138) is well worth pondering in this connection, and will serve to explain how the idea of an "artist" dominates the popular conception of the consummate physician—as is, indeed, involved in the German word "Arzt," which Becker rightly derives from the Low Latin "artista." Noteworthy, too, is the fact that the intellect here typified is always genial, always repays the confidence it invites by possessing the patient with the belief that his malady is indeed of personal interest to his adviser, who considers, and pronounces, and prescribes as if he were in the other's place. That is what Celsus means when he talks of the "hilaris vultus" of the ideal consultant—what Horace implies by the "deformis ægrimoniam dulcibus alloquitur." The character thus equipped by nature becomes more and more developed by experience, till, as statesmen and men of letters, and indeed the moral and intellectual grandees of every age, combine in attesting, humanity appears in no more admirable or lovable form than in that of the "ideal consultant."

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

Original Communications.

ON THE EARLY DIAGNOSIS AND TREATMENT OF SEPTIC PERITONITIS.\*

By HENRY L. ELSNER, M. D.,

PROFESSOR OF CLINICAL MEDICINE, SYRACUSE MEDICAL COLLEGE, SYRACUSE, N. Y.

While bacteriologists and pathologists have taught us much with regard to the various inflammatory processes affecting the peritonæum, the clinician has yet much to learn of the early diagnosis and treatment of septic peritonitis.

While we have been taught by the brilliant achievements of abdominal surgeons that the peritonæum is no longer a *noli me tangere*, their experience has established the fact beyond controversy that septic material is not tolerated by the peritonæum. There is no serous surface which revolts so quickly against the invasion of any agent capable of carrying infectious material as the peritonæum.

In this short introduction, the time for which is necessarily limited, I am to say a few words to you on the subject of the early diagnosis and treatment of septic peritonitis, and in discussing it I shall confine myself strictly to those forms of peritoneal inflammation dependent upon putrefactive and septic agents for their propagation.

This at once involves a question which I see from your programme you have relegated to another—whether there exists, in fact, an idiopathic peritonitis. While my views upon this subject may differ from those of many of you, my clinical experience has taught me that idiopathic peritonitis is a disease which is rarely found, and the existence of which may indeed be doubted. I shall hold, therefore, that much the larger number of cases of peritonitis which we are called upon to treat are either septic from the beginning or become so before they have run their course.

This being my opinion, it is hardly necessary for me to tell you that in all forms of septic peritonitis it is the duty of the physician to ascertain, if possible, the pathogenic factor which was the original cause of the septic process. While Habershon, in over five hundred autopsies, claims to have found no single case of peritonitis in which he could not establish the fact that disease existed in some organ besides the peritonæum, the physician finds in many cases great difficulty in determining the source, ante mortem, of the septic process.

When we take into consideration the innumerable sources from which a septic process may attack the peritonæum, we find that there is reason for our repeated failures. It is, nevertheless, necessary for us to bear in mind the fact that we are dealing with a secondary process, and it should be our aim to make a most rigid inspection of all portals through which the materies morbi may gain entrance, in conjunction with the most cautious and searching investigation into the preceding history of the patient, as well as a careful consideration of each and every symptom present.

\* Being part of a discussion before the Onondaga Medical Society January 28, 1892.

The diagnosis of those forms of septic peritonitis which follow injury to the abdominal wall—surgical operations either for abdominal diseases, including hernia, diseases of the genito-urinary tract, or puerperal processes—is easily made. We have in all of these cases the previous history, which aids us. Peritoneal symptoms would be more likely to be due to a septic than to any other process.

Inflammatory diseases in the neighboring organs, which give rise to peritonitis by contiguity, are not particularly difficult of diagnosis. The cases which interest us most are those of perforative peritonitis, which may be either circumscribed or diffused, and it appears to me safely considered to be septic.

It has been my misfortune to see, in the course of my experience, a number of cases where a septic process followed perforation of the stomach wall, either from round ulcer or from cancer. In these cases there was present the collapse which followed perforation, the characteristic appearance of the patient, more or less reaction, and then the evidence of diffuse peritonitis; all of these cases ended fatally.

I have also had some experience with septic peritonitis, both localized and diffused, following perforation of tuberculous ulcers of the intestine, in which there was no preceding tuberculous peritonitis.

The diagnosis in such cases is easily made. The preceding history of tuberculosis, with alternating diarrhœa and constipation, the presence of symptoms of perforation, collapse, without, as a rule, much reaction, following a short period of septic peritonitis, with rapid death, would be sufficient to warrant the diagnosis.

The most frequent cause of septic peritonitis has been disease of the vermiform appendix, and it appears that in this discussion our time can be best spent in considering the early symptoms of peritonitis which follow the various forms of appendicitis.

The literature of this subject has grown amazingly during the past ten years, and while many lives have undoubtedly been saved as a result of our better understanding of this subject, there has not been a single article written, to my knowledge, which can be said to offer positive signs or symptoms for the detection of septic peritonitis, in cases where it develops without preceding well-marked symptoms of vermiform disease in which such disease really pre-existed.

If this question could be solved—if we could diagnose the condition of the vermiform appendix before its disease makes itself manifest by the sudden development of either a localized or general peritonitis—much would be gained.

While we may not profit greatly from a consideration of the frequency with which the vermiform appendix is found to be diseased, it is, nevertheless, interesting for us to remember that the statistics of Matterstock, Toft, and Kraussold show an amazingly large proportion of diseased appendices. It is hardly credible that every third person whom we meet between the ages of twenty and seventy has some trace of inflammation in the vermiform appendix. Equally surpris-

ing is the fact that five per cent. of all bodies examined show evidences of ulceration in the vermiform appendix. Kraussold maintains that five per cent. is too low a figure.

These statistics, and the result of our own post-mortems, have been sufficient to arouse in us a desire to explain the cause of this enormous amount of appendiceal disease. If all diseased appendices were followed by a perforative or septic peritonitis, that would at once become the most frequent cause of death.

If you will allow me, I will offer an explanation for these many evidences of appendiceal disease. To my mind, there can be no doubt that there is a latent appendicitis; that this latent appendicitis in many cases runs its course without sufficient symptoms to make its existence known; that it may remain latent for years; that there may remain within the appendix products of inflammation, foreign substances, and micro-organisms without exciting the least suspicion; that in some cases a slow, chronic, but yet protective peritonitis of a localized character surrounds the appendix, preparing the way for its perforation, guarding the general peritonæum at the same time. In other cases a latent appendicitis may lead to the changes which are found in patients who die from other diseases, where the appendicitis never gave rise to more than local and unrecognized disturbance.

That this theory is not without foundation must be admitted when we consider the frequency of diseased appendices found post mortem and the evidences which we have all found of a perityphlitic inflammation. Remember, please, that when I use the term "perityphlitic" it refers to a process secondary always to appendiceal disease.

On the other hand, this theory would account for those cases in which we have, without warning, a rapidly spreading diffuse and septic peritonitis as the result of perforation of the appendix. The appendicitis, latent for days or months, suddenly causes by a fresh catarrhal inflammation an increase in the contents of the appendix; either dilates, its circulation is interfered with, or, by pressure, a localized spot becomes gangrenous, perforation results, with immediate septic peritonitis.

This explains still another fact, and that is that the serious cases of appendicitis are those in which we have the fewest symptoms of local disease. Those cases of appendicitis in which there is tumor formation, well pronounced, are more likely to have accompanying adhesive inflammation to guard the general peritonæum.

Experience has still furthermore established the fact that a large number of these cases do not come to us for diagnosis or treatment until the appendix is perforated and the peritonitis has commenced. The diagnosis of a septic peritonitis following perforative appendicitis, in which there has been tumor formation, need not detain us for its consideration. It would be a presumption on my part.

The difficult cases to detect in their incipency are those in which there is perforation *without preceding tumor, and it is these cases which we must detect early if we are to reduce the mortality from appendicitis.* A septic peritonitis following will run its course rapidly, and with certainty lead to death unless relieved early.

In these cases we must be guided by both subjective and objective symptoms. Most of the patients, if closely questioned, will give a history of preceding indigestion, both intestinal and gastric. There may or there may not have been preceding pain in the right inguinal region. As a rule, there has been no appreciable elevation of temperature. Suddenly a chilly sensation follows a few hours of pain, localized over the right inguinal region, rarely a well-defined chill. The pain may become intense at once, the facial expression markedly changed, the surface circulation impeded. The patient now refers all pain to the actual seat of the disease.

As a rule, we are not even called at this stage. The patient, imagining that his trouble is a simple colic, postpones medical attention, but septic peritonitis has nevertheless commenced. We find the abdominal wall in the region of the appendix most tense, tender, and possibly slight localized œdema. The abdominal wall in its lower half is everywhere abnormally tense and tender also. The patient already lies on his back with knees drawn up; the pulse is at first tense, but does not remain so long, becoming more rapid as the disease progresses. The temperature is slightly elevated, rarely above 102° to 102.5°. The McBurney point is a valuable aid in the diagnosis of this form of peritonitis when the patient is seen early.

With the above history and the presence of the McBurney point the diagnosis of a peritonitis following appendicitis can be made. Want of time prohibits an enumeration of the many other symptoms, but in these forms of perforative septic peritonitis, either from perforation of the vermiform or perforation of other abdominal viscera, we have in the effacement of liver dullness a very reliable symptom, when the perforation has not been preceded by adhesive peritonitis to limit or encapsule the escaping gas and fœces.

To those of you who have studied the views of the various writers on this subject it must appear surprising to find such a wide difference of opinion as to the value of effacement of liver dullness in cases of perforation or air in the free peritoneal cavity.

Flint wrote a paper in which he held that this was one of the most characteristic signs of perforation. The difference of opinion with regard to the effacement of liver dullness, it appears to me, can be reconciled if we take into consideration the two great sources of error. First, an unusually distended transverse colon, by its presence between the liver and abdominal wall, yielding on percussion tympany anteriorly over the area of normal liver dullness without perforation existing.

Second, perforation in those cases where, as the result of adhesive inflammation, encapsulation, bands, or from other causes, air or gas is held within a circumscribed area, or in the lower half of the abdomen, without effacement of liver dullness. The careful examination of the abdomen would reveal the presence of these sources of error by placing the patient upon the left side and percussing in the axillary line, on the right side over the liver, from the eighth rib downward, the presence of free air in the peritoneal cavity showing itself by a disappearance of dullness in that

line, while there would be a persistence of dullness if the anterior tympany had been caused by the distended transverse colon.

Typhoid ulceration, perforating, may give rise to either general or circumscribed peritonitis. If adhesive peritonitis precedes perforation sufficient to include the ulcer in a capsule of fibrinous exudate and adherent intestinal coils, general peritonitis may not result and liver dullness may persist. Usually, however, there is more or less septic peritonitis accompanying these rapidly fatal cases.

Recurrent appendicitis has never, in my experience, given rise to more than localized inflammation. Indeed, most of these cases are so surrounded by dense bands of new connective tissue and peritoneal adhesions that the general peritonæum is surely guarded.

I have seen but four cases of recurrent appendicitis. Three of these recovered perfectly; one committed suicide after repeated attacks, the post-mortem showing dense bands and peritoneal adhesions, the vermiform appendix no longer recognizable; a thickened cord of connective tissue was found over its original seat.

I will not dilate longer on the other early symptoms of septic peritonitis. It does not appear to me to be necessary to do so before a body of educated physicians. I wish only to call your attention to the fact that all forms of septic peritonitis are early in their course associated with extreme prostration, in many cases collapse, and that in all cases the well-understood physical signs of peritonitis are present.

We are not to forget those forms of septic peritonitis in which the disease remains localized owing to preceding adhesions. Here there is usually tumor formation, and there may be pus accumulation. In these cases there may or may not be perforation of a hollow viscus. There is often, if this localized peritonitis is neglected, breaking down of the inclosing structure, and a rapidly fatal diffuse septic peritonitis.

With regard to treatment, the indications are offered by the process which led to the septic peritonitis. It is safe to say that this form of peritonitis is rapidly becoming a surgical affection, and in no other disease is concerted action of physician and surgeon more important or more necessary. The successful treatment, whether medical or surgical, must necessarily be instituted early.

The operative treatment of septic peritonitis, I see from your programme, has been referred to others more competent to cope with the subject than myself. I wish to add, however, my disapproval of too hasty operative interference in cases where there are evidences of protective adhesions, and my hearty approval of early and prompt operation in cases with or without tumor, but where a tense abdominal wall, tenderness at the McBurney point, and evidences of spreading septic peritonitis are present.

The tendency now, since the opium treatment of peritonitis is being more and more slighted, will be to give salines in all forms of that disease. Inasmuch as the majority of cases of septic peritonitis are due to perforation of some one of the hollow viscera, we must warn against the indiscriminate and careless use of any measure which

will increase the trouble, and prevent by its physiological action the formation of adhesions or agglutination.

While I do not advocate the opium treatment which was instituted by the late Alonzo Clark, I, nevertheless, believe that in many cases a judicious use of morphine hypodermically materially relieves suffering and adds to the chances of the patient's recovery. In all cases the extreme exhaustion and collapse require judicious stimulation and a proper liquid diet.

In conclusion, I wish to express my belief in the treatment of all forms of septic peritonitis arising in the puerperal period by an early and thorough antiseptic cleansing of the uterine cavity; if a simple washing out is insufficient, let us remember that the curette has in a few alarming cases done yeoman's service.

## PLACENTAL LOCALIZATION BY ABDOMINAL PALPATION.

By T. RIDGWAY BARKER, M. D.,

DEMONSTRATOR OF OBSTETRICS IN  
THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA;  
OUTDOOR OBSTETRICIAN TO THE PENNSYLVANIA DISPENSARY.

In the scientific study of any subject it is necessary that we employ scientific means; otherwise our conclusions have no foundation in fact, and may be likened to the observations of the balloonist, whose statements, while they are perhaps true, lack one essential element—verification. With this thought uppermost in our minds, we are prepared to investigate the truth of the assertion "that the placenta can be definitely located by abdominal palpation." It would appear extremely doubtful, however, if its position can be determined when situated on the posterior wall of the uterus, as the intervening tissues, liquor amnii, and fœtus must prove formidable obstacles to the practicing of palpation with this object in view.

Should the placenta, on the other hand, occupy an anterior position, then the task becomes a comparatively simple one under favorable circumstances. In cases of placenta prævia this somewhat novel method of localization has been more extensively employed than in any other form, owing to the great importance of making an early diagnosis, thereby materially lessening the dangers to both mother and offspring.

While the researches of Spencer, of the University College Hospital, London, have been conducted with great care and thoroughness, and have been verified in seven of his cases by subsequent intra-uterine manual explorations, yet, withal, other investigators have no such success to report, though possessing equal skill and knowledge.

Duncan states that he has tried and always failed, while Galabin agrees with Spencer in a measure, but does not think localization can be successfully practiced invariably or as a general rule.

If we turn to Barnes in our dilemma, we find he expresses himself very clearly and unmistakably on this subject, going so far as to declare that he has "confirmed Spencer's observations, that when the placenta is situated in the upper zones and in front of the uterus, the wall is

thickened and raised above the level of the general smooth surface of the uterus." This he has confirmed by auscultation. Thus we see several unquestionably accurate observers of undoubted ability arranged on opposite sides of the question, occupying what would at first appear irreconcilable positions, but which is not really the case, for their investigations, it is but fair to assume, were carried on under radically different conditions. Spencer's cases of placenta prævia in which he was able to diagnosticate the location of the placental site occurred in women with thin abdominal parietes, which rendered manipulation much easier and permitted a thorough outlining of the uterus, while those examined by Duncan were presumably women with large adipose deposits in the abdominal walls, masking the contour of the uterus and materially interfering with the efforts directed toward placental localization. One could scarcely expect to experience Spencer's sensations "of an elastic mass, of the consistence of a wetted bath sponge, which keeps the examining fingers off the head" in obese pregnant women. Nor could one define the edge of the placenta, which is described by the same author "as conforming to the shape of the segment of a circle in which all is obscure to the touch, while outside the head or other part of the child is plainly felt."

To accomplish such a delicate procedure it is absolutely necessary that the abdominal walls shall be thin and the uterus not unduly distended by amniotic fluid. That such localization may be effected under favorable circumstances in a certain percentage of cases there appears to be no doubt.

One is scarcely prepared, however, to rely implicitly upon this method, since mistakes have already been made, and the knife carried through the placenta in the performance of a Cæsarean section when the placenta was supposed to be at some distant point from the line of incision. The existence of a placenta succenturiata should also be borne in mind in this connection. If we employ this method when about to perform an abdominal section for the release of the imprisoned fœtus, we should not fail to take the additional precautions laid down by Leopold, of Dresden, with reference to determining the site of the placenta after making the abdominal incision, in order to avoid including this vascular structure in the uterine wound.

The diagnosis as to the anterior or posterior insertion of the placenta may be made out by the following relations of the oviducts to the fundus of the uterus: "When the major portion of the uterus is anterior to the insertion of the tubes, the placenta is anterior, and *vice versa*."

Thus we have a definite rule for diagnosticating the situation of the placenta, which is less likely to mislead the operator than that by abdominal palpation.

To sum up, then, the value of abdominal palpation in locating the displaced placenta, one is justified in considering it an additional means of verifying the existence of placenta prævia; and, while characterized by clearly defined physical signs, it can only be practiced satisfactorily when the abdominal walls are thin and the uterus is not unduly distended by liquor amnii.

In Cæsarean section, or one of its modifications, we

ought not to rely upon this procedure alone, but should deem it necessary to re-enforce our opinion by observing the situation of the uterus with reference to the Fallopian tubes as laid down by Leopold.

## SOME PREVALENT ERRORS RELATING TO "EYE-STRAIN" AS A CAUSE OF NERVOUS DERANGEMENTS.

WITH ILLUSTRATIVE CASES.

BY AMBROSE L. RANNEY, A. M., M. D.

(Concluded from page 656.)

CASE VI. *Complete Nervous Prostration (of over Five Years' Duration) with Constant Pain in the Head, Inability to use the Eyes, and to walk but a Few Steps.*—Miss F., aged twenty-one years.

*Family History.*—Maternal aunt and five paternal relatives died of phthisis; two cousins had chronic chorea.

*Eye Defects.*—Patient had hyperopia (latent) of 1.25 D. and exophoria (manifest) of 2°. A latent hyperphoria of 2° was subsequently discovered.

*History of the Case.*—This young lady was brought into my office (September 29, 1886) by two assistants, who were obliged to carry her from the carriage. For several years she had been carried daily from her room to the library of her father's house, and, after reclining in a chair for a few hours, she would be again carried to her bedroom. She could manage with difficulty to walk slowly across a room. She had not been able to write, read, sew, or see her most intimate friends for five years on account of a constant pain in her head, which was rendered intolerable by any use of the eyes or excitement. Her symptoms began while at boarding school, from which she was removed to her home in a recumbent posture and by easy stages.

*Treatment and Results.*—I used static electricity upon this patient for some weeks with a slight improvement in her power of walking, but no relief to her head.

I then persuaded her to consent to a relief (by graduated tenotomies) of her abnormal eye-tension. Tenotomies were then performed upon her left superior rectus and both externi within the space of two weeks. From that date her improvement was very rapid. She was sent home a few weeks later practically cured.

A letter from her physician, received by me, says:

"Your patient is the wonder of this region. She rivals the 'Jersey Lily' in her feats of walking."

Before this patient was sent home she ascended and descended five flights of stairs daily, and averaged over a mile's walk each day without a companion to assist her.

The last report from this case was made about one year ago when the patient called to say that she "was engaged in teaching physical culture in a ladies' school." The improvement gained by eye treatment has therefore been demonstrated to be not only permanent, but progressive.

CASE VII. *Complete Nervous Prostration (of Sixteen Years' Duration), with Terrible Attacks of Neuralgia of the Stomach and Persistent Trembling of the Head, Face, and Limbs.*—Mrs. G., aged forty-two.

*Family History.*—Several blood-relatives died of phthisis; father and brother died of phthisis.

*Eye Defects.*—The patient was found to be emmetropic (when under atropine). Esophoria (manifest) of 8° existed.

*History of the Case.*—This is quite as striking a case as the

one last narrated, although of a different character. The patient had been for sixteen years a chronic invalid. She was unable to bear the least excitement. Even the companionship of her family for an evening was at times too great a strain upon her nervous system. She was at times a great sufferer from severe paroxysms of neuralgia of the stomach, and frequent attacks of alarming shortness of breath and a sense of impending suffocation would occur. I personally witnessed one of these attacks in my office, and it was entirely free from a trace even of hysteria. It was of much shorter duration than an asthmatic attack, and seemed to be due to a spasm of the larynx. She became markedly cyanotic, and suffered alarming shortness of breath.

In addition to these symptoms, this patient suffered from an uncontrollable trembling of the facial muscles and limbs when at all startled or excited. She had been for years unable to attend places of amusement or to bear physical exertion.

*Treatment and Results.*—Much to my surprise (as she had a marked phthisical history), an examination of her eyes showed no refractive error (even when under the influence of atropine). She showed, however, a very high degree of esophoria, and a partial tenotomy was performed upon both of her interni. The effect was magical. She recovered her health completely within two months, and is to-day able to endure as much as when a young girl. One of the last reports from her, some time ago, states that she had "shopped all day and attended the theatre in the evening." An old friend of the family lately alluded to the case, in my presence, as one "not of cure, but of resurrection."

Five years have now elapsed since this patient was relieved of her "eye-strain." During this period no return of her old symptoms has occurred; nor has she had to resort to drugs or doctors for relief of any physical ailment.

*CASE VIII. Nervous Prostration, with Symptoms of Melancholia, Confirmed Sleeplessness, Confusion of Mind, and Constant Headache.*—Miss B., aged forty, single.

*Family History.*—One sister was for over a year a victim to "complete nervous prostration." Father is a very nervous man.

*Eye Defects.*—Vision  $\frac{2}{3}$ , without atropine. Under atropine, a latent hypermetropia of + 0.75 s. in each eye. Patient had never used a glass for reading, but accepted + 1.50 spherical glass. Esophoria, 3° (which ultimately, under influence of prismatic glasses, exceeded 7°). Adduction, 23°. Abduction, 5°. R. sursumduction, 1° +. Left sursumduction, 2°. The adducting power later on exceeded 43°, and the abducting power fell below 3°. At no time did homonymous diplopia disclose itself (with or without a red glass).

*History of the Case.*—This lady had for some years been doing an excessive amount of mental work. Her profession required an enormous amount of reading. This had been done largely at night. Although small in stature, she had always been vigorous and had taken an unusual amount of exercise. She had always considered her eyes very strong, and was loath to believe, when she first came under my care, that her eyes could constitute a factor in her serious nervous condition. Furthermore, she was strengthened in this belief by the fact that she had not long before consulted an oculist of prominence, who had stated that he found no defect requiring treatment or glasses, and who had sent her to one of his friends (a specialist in nervous diseases) for treatment.

The "break-down in her health" began about twelve months before she came under my care. It was attended with an extreme and persistent loss of sleep, a loss of emotional control, an utter inability to read or sew (which aggravated all her symptoms), a more or less constant headache, an inability to concentrate her intellectual faculties for any length of time, and

an aggravated type of mental depression. She feared, and had every apparent reason to fear, that her professional labors were imperiled and that her mind might possibly give way. The neurologist, who endeavored to build her up by tonics, rigid diet, rest, etc., assured her (after some improvement had occurred) that he feared at first that "melancholia" might be the end of the case. At his advice, she spent the summer at the sea-shore; but, beyond a certain point, she failed to progress satisfactorily, and her headache and sleeplessness would at times be as bad as ever. Any attempt to prepare herself for her fall engagements would cause a return of her old symptoms to a very marked degree, accompanied by physical weakness, mental fatigue and depression, extreme despondency, and a lack of control over her emotions. After any attempts at study, she would frequently lie awake most of the night. This was her condition when she first came under my care.

*Treatment and Results.*—In this case a full correction of the hypermetropia was made for distance, and + 2.00 spherical glasses were given for reading, as she showed some failure of accommodation. Prisms of various strengths were employed over her distance and reading glasses for about two weeks, and 7° of latent esophoria were found to exist. This was rectified by a graduated tenotomy of one internus and the prisms were then discontinued. During this interval the patient had improved very rapidly, had become very dependent upon her spherical glasses, and become cheerful and hopeful of recovery. She had, moreover, entirely regained the normal power of sleep. During this interval she had frequently slept twelve hours without awakening and without recourse to any drug. As atropine had been used during the early part of the treatment, she had been allowed during the two weeks of treatment to use her eyes very little in reading or study. During the following two weeks two degrees more of latent esophoria disclosed itself. For the relief of this defect a prism was combined with the spherical glass worn over the eye which had not been subjected to a tenotomy.

For the past twenty months this patient has been able to fill all her engagements without any return of her bad symptoms. She has read and studied at night, attended church and places of amusement that previously she dared not attend, has accepted more work than for some years past, and has continued to sleep well and enjoy perfect health. During this interval she has taken no medicine, nor has she been restricted by me in her diet or in any other way. Her reading-glasses have been increased to + 2.50 s.

A graduated tenotomy of the internus of both eyes was eventually performed, in order to properly adjust the balance between the two eyes, and the right superior rectus was also subjected to a graduated tenotomy for a right hyperphoria that disclosed itself.

During one of her last visits this patient said: "I think I am stronger to-day and have better health than I have had for many years. I certainly do my work with less fatigue, and enjoy things that my ill-health has previously debarred me from."

In a letter received a few months ago this patient says: "I can out-eat, out-sleep, and out-walk any woman in this place."

Just as this article is going to press, the sad news of this patient's death reaches me. A relapse of her nervous symptoms occurred a few days before her death, after a very severe winter of persistent labor attended also with great care and much worry and anxiety. Moreover, an inquiry into the causes of this relapse discloses the fact that she had disobeyed my instructions and discarded her spherical glasses

for distance after her health had been apparently restored; that she had even read for hours daily without her reading-glasses; and that she had seriously overtaxed her mind and physical strength in many ways.

**CASE IX. Melancholia with Morbid Impulses, associated with Great Mental Confusion and Distress and an Obstinate Neuralgic Affection of the Prostate Gland.**—Mr. S., aged twenty-three, unmarried.

**Family History.**—The mother of the patient suffers from neuralgia and headache. The paternal grandfather had paralysis. The paternal grandmother was "extremely delicate." One brother suffers from headaches. Another brother is very excitable and of a highly nervous temperament. No case of consumption has ever occurred in any branch of the family.

**Eye Defects.**—Hyperopia (latent) of 2.50 D. Esophoria (manifest) 4°. Subsequently, 12° were elicited prior to any operative procedure.

**History of the Case.**—This patient had been under medical care for many months for a prostatic neuralgia, and had derived no benefit from local or general treatment. He developed *melancholia*, and would frequently retrace his steps for several blocks, during a stroll, in order to touch some object which he felt he should have touched when he passed it. The use of his eyes intensified his mental symptoms markedly. He also suffered from morbid fears. He had never had venereal disease.

**Treatment and Results.**—After partial tenotomies were performed upon his interni, and his hypermetropia was corrected by +1.50 spherical glasses, his recovery was very rapid and complete. He has had no abnormal mental symptoms or neuralgia of his prostate since the first operation (now nearly six years). His father, one brother, and a sister have since been examined by me, and all had very marked eye defect.

In some respects this is one of the most remarkable cases I have yet observed. The mental condition of the patient, prior to the relief of eye tension, was such as to justify the worst forebodings. Neither he nor his family had ever suspected any eye defect in spite of the fact that his "latent" hyperopia was of a very high degree (nearly 3 D.), and his "latent" esophoria was of an equally high degree. His prostatic neuralgia was of a severe and intractable type, and its cause could not be discovered; yet it disappeared at once after a free operation upon the interni.

The change in the mental condition of this patient after the relief of his eye-strain manifested itself at once in his desire to assume active employment. He immediately turned his attention to his profession (that of art), in which he soon gained an enviable fame.

**CASE X. Nervous Prostration, combined with Sleeplessness, Pain in the Head, Mental Confusion, Car-sickness, etc.**—Mr. H., aged forty-six, manufacturer, married.

**Family History.**—Both parents lived to seventy-six years. Two paternal uncles died of phthisis. No hereditary tendency to nervous diseases.

**Eye Defects.**—Vision  $\frac{2}{3}$ , without atropine. Under atropine a latent hypermetropia of +1.00 s. in each eye. Patient had never used a glass for reading. Esophoria, 5° (after using prismatic glasses for a short time, the patient showed esophoria of 13°). Adduction, 24°. Abduction, 4°+. Later on, the adduction exceeded 50°, and the abduction fell to 0. Homonymous diplopia with the red glass over one eye was usually present, and at times without the red glass.

**History of the Case.**—This patient had been a perfectly well man and had carried on a very large business up to fifteen years ago. At this time, while attending a sale in New York, he was suddenly seized with a dizziness, faintness, and a sore feeling in

his head. These symptoms lasted for three years in spite of all treatment, during which time he suffered severely from sleeplessness, extreme nervousness, and soreness in his head. He was unable to look out of a car window while traveling without great distress.

He had suffered all his life from obstinate constipation, and had taken cathartics so regularly that now any cathartic water causes intestinal hæmorrhage.

When this patient first came to me he was able, by the most careful diet, regular habits, and by retiring at eight or nine o'clock, to carry on his enormous business only with the greatest difficulty because of the following symptoms: Inability to sleep at night, which at times was very distressing and persistent; extreme nervousness after the slightest fatigue; mental depression without any cause; hot flashes up and down his spine; pain in his shoulders and across his back. His insomnia was often prolonged and very exhausting after any slight excitement or fatigue.

**Treatment and Results.**—The treatment of this patient consisted at first of the wearing of prisms to relieve the esophoria, and later on of graduated tenotomies on both internal recti. Subsequently, +0.50 s. glasses were given for constant wear, and +1.00 s. glasses for near work. The improvement in his condition was marked and continuous from the first, and he writes that he is so busy and feeling so well that he can not find time to have the slight remaining esophoria corrected. An extract from a letter received from him two months after the operation on his eyes speaks for itself. He says: "Seemingly I am all right, feeling better every day; have not had a headache for a month; appetite good and I sleep well." Over two years have now elapsed without any return of his former ill health, during which time he has constantly been engaged in active business pursuits.

**CASE XI. Complete Nervous Prostration, with One Year of Confinement in Bed and Chronic Bladder Trouble.**—Mrs. W., aged fifty-five, married.

**Family History.**—Not taken.

**Eye Defects.**—Hypermetropia, +1.75 s. Presbyopia (uses +4.50 s. for reading). Esophoria, 7°. Adduction, 23°. Abduction, 3°+. Later on she disclosed: Right hyperphoria, 3°; right sursunduction, 6°+; left sursunduction, 2°—.

**History of the Case.**—This patient is the wife of a prominent physician, and, as such, has had the benefit of the best medical talent of the State in which she resides. She had always been a delicate woman up to the time when my professional opinion of the case was asked. For a year or more before I first saw her she had been a victim to nervous prostration and confined most of the time to her bed or room. Her life had been despaired of during this interval at times, and the case seemed to present problems in diagnosis which puzzled the best medical men whom she had consulted. When she had gained sufficient strength to allow of her being moved with safety, her husband was advised to take her to a Southern climate. On her way to Florida he was advised to consult me in reference to the case, when he passed through New York.

When I first saw this patient she was in a state of extreme physical and mental depression, was unable to walk for even short distances without great fatigue, was sleepless and despondent, and was brought to my office in a carriage from a hotel not far from my residence.

**Treatment and Results.**—At the first visit prisms were given to relieve the esophoria, and in five days a graduated tenotomy was done on one internal rectus. The patient began to feel the benefit of this step from the first. The second day after the tenotomy she reported that she had walked a mile and a half—a thing which she had not done for over a year. Five days after

the first tenotomy, a second one was performed on the other internal rectus, prisms having been worn in the mean time. Two days following this the patient walked five miles, visited an art museum in the morning, and attended a theatre in the evening. In spite of the unusual fatigue and excitement, she was still sleeping well and feeling stronger than for many years. With the improvement of her general health came an entire cessation of an obstinate bladder trouble which had given her annoyance for many years, and was probably due to her weak muscular and nervous condition. The pain in the bladder, which was probably of the neuralgic type, ceased after the relief of the eye tension, and has never returned.

After an interval of four months, during which she had been comparatively well, she returned to New York to complete her treatment. A high degree of hyperphoria was found, and prisms were combined with her hypermetropic glasses to relieve it. With these glasses the patient passed eight months of almost absolute freedom from distress of any kind, when a graduated tenotomy was performed and the hyperphoria prisms removed.

At the present time she is sleeping well, is able to attend to her household duties, can walk long distances, has taken no medicine for over a year, and is regarded by her husband and friends as restored to perfect health.

**CASE XII. Facial Neuralgia, so Severe as to prompt Suicide and Uncontrollable by Drugs.**—Mr. L., aged twenty-three, single, minister of the Gospel.

*Family History.*—Father has severe headaches; one sister has severe headaches; all paternal relatives have headache or neuralgia.

*Eye Defects.*—Hypermetropia (under atropine), + 2.00 s. Esophoria, 6°. Adduction, 28°. Abduction, 2°. Right sursumduction, 2°. Left sursumduction, 2°.

The hypermetropia and most of the esophoria were latent.

*History of the Case.*—The patient began to have neuralgia ten years ago, and for the past five years the attacks have become more frequent and severe. They generally start in the left orbit and extend to both orbits, and at times are frightfully severe. They occur at intervals varying from six hard ones a year (each with four or five days of agony) to one every two or three weeks. He has comparatively slight headaches very often. Any excessive use of eyes or overwork brings on a neuralgic attack. He has suffered with quite constant pain in the back, and has had some asthenopic symptoms, smarting of eyeballs, pain after reading, etc. No drug has ever seemed to control these symptoms, and he was sent to me by his physician for advice. He came during one of his severe paroxysms of neuralgia, which had lasted for three or four days, in spite of all that his physician could do. Although hypodermic injections of morphine had been used every night, the pain returned with increased severity in the morning. So intense was his agony that he declared something must be done at once, as he feared that he could not restrain much longer his suicidal tendency.

*Treatment and Results.*—Tests were made upon his eyes as accurately as possible under the circumstances, and atropine was dropped into his eyes at once to determine his hypermetropia. He was told to protect his eyes from the light by a pair of dark glasses and return in two hours. He came in smiling at the appointed time, saying that his neuralgia had entirely disappeared. Two dioptries of hypermetropia was found, and a + 1.00 s. glass was given for constant wear. Later graduated tenotomies were done upon both internal recti for the relief of the esophoria, and a stronger glass (+ 2.00 s.) was given for reading. Since then he has had no attack of neuralgia, and has been perfectly well for two years. He occasionally, after severe eye work, has some slight symptoms of his old asthenopia.

**CASE XIII. Nervous Prostration, with Digestive Disturb-**

*ances and Great Physical Weakness.*—Mrs. W., aged forty, married, three children.

*Family History.*—Father died of softening of the brain; mother died of phthisis; one sister died of cirrhotic kidney and uræmic convulsions.

*Eye Defects.*—Hypermetropia, + 1.50 (under atropine). Esophoria, 4°. Adduction, 45°. Abduction, 4°. Right sursumduction, 2°. Left sursumduction, 2°.

*History of the Case.*—This patient had always been delicate, and had suffered some during her girlhood from sick headache and weak digestive functions. Six years previous to the examination of her eyes made by me, she had suffered from an attack of nervous prostration, with extreme physical weakness. At this time she was treated for several months by a prominent gynecologist for uterine trouble without very marked improvement in her general health. She was then placed under the care of Professor Weir Mitchell, of Philadelphia, and remained several months in his hospital undergoing the "rest treatment." For about a year her physical condition seemed to be very much improved; but at the end of that time her old symptoms returned in a very marked degree. She was then treated by static electricity for a period of several weeks without any very marked benefit. The administration of drugs and stimulants seemed to exert little if any control over her debilitated state.

At my suggestion, she consented to submit to a tenotomy for an esophoria of not very high degree.

*Treatment and Results.*—A graduated tenotomy was performed upon the left internus with very satisfactory results upon her eye tests. Within a month she had almost entirely regained her former vigor, and could walk several miles without fatigue. During the past five years she has suffered no relapse, and, in an interview lately held with her, she stated "that she had but little use for doctors, who formerly were constant visitors in her household."

**CASE XIV. Nervous Prostration, accompanied by an abnormally Large Pupil in One Eye, Insomnia, and Extreme Physical Weakness.**—Mrs. J., aged forty-five, married. Has had three children.

*Family History.*—Not taken.

*Eye Defects.*—Hypermetropia and astigmatism of + 1.50 s.  $\odot$  + 0.50 c. in each eye (under atropine). Right hyperphoria,  $\frac{1}{4}$ °. Esophoria, 0 — 1°. Adduction, 21°. Abduction, 8°. Right sursumduction, 2° +. Left sursumduction, 2°.

*History of the Case.*—For many years patient has been a delicate woman, becoming easily fatigued, and suffering more or less after fatigue from insomnia and extreme nervous debility. For the past ten or twelve years one pupil has been very much dilated. She had consulted an oculist of prominence in Montreal concerning this condition, but his treatment failed to give any permanent benefit. During the past twelve months the insomnia and nervous prostration had become very much intensified, and the patient had become so weak physically as to alarm her family. Any attempts at walking, attending places of amusement, or making ordinary social visits were followed by a marked increase in the symptoms. Her husband, a prominent physician, feared a complete physical collapse. One pupil was found to be more than double the size of the other.

*Treatment and Results.*—The treatment consisted of a full correction of the hypermetropia and astigmatism for distance by glasses, which the patient was instructed to wear constantly. Under these conditions her muscular tests seemed to be modified favorably. The patient was instructed to return home and to return for further observation after wearing the glasses for a couple of months. Even before her return there had been a marked improvement in her symptoms. Two weeks after her return the following report was made by her husband: "My

wife appears much better and more cheerful than for many years, the pupils are of equal size, appetite good, and the insomnia much relieved; is able to walk two miles without fatigue and enjoys the exercise, goes out evenings, and feels no unusual fatigue from lectures, concerts, and sermons." A report one month later says: "My wife appears to enjoy life as she has not done for many years. There has been a very slight return of her old enemy insomnia, but not to an alarming extent. She hopes to see you again in the near future."

In this case sufficient opportunity has not yet been afforded for a complete examination of the eye muscles. It is possible that there may be some lurking defect of equilibrium in addition to the error of focus. One thing, however, appears to be clearly established—*i. e.*, that her ill health and insomnia were directly dependent upon a condition of the eyes that had exhausted her vital forces and was keeping her in a state of extreme physical depression.

*CASE XV. Aggravated Type of Chronic Chorea, accompanied by Deformity, Headache, Asthenopia, and Inability to Work.*—Miss C., aged twenty-six, single.

*Family History.*—Not known.

*Eye Defects.*—Hypermetropia, + 0.75. Esophoria, 20° (mostly latent). Left hyperphoria, 3°. Adduction, 22°. Abduction, 5°. Right sursumduction, 2°. Left sursumduction, 5°.

*History of the Case.*—The patient was a poor factory girl that was sent to me by a medical friend (Dr. O'C.) in Massachusetts to see if anything could be done for her. No one who had seen her could make a diagnosis. Since her tenth year she had suffered with neuralgic headaches, asthenopia, and persistent trembling in her hands and arms. For the past four years there has been a stiffness and rigidity of the neck, accompanied by severe pain in the neck and "choking spells" when she attempts to speak or when excited. There is also marked contracture of the hands and arms.

Her appearance when she came to me was one of remarkable deformity. Her chin seemed to be held firmly in the region of the fourth button of her dress. Both upper limbs were contracted in the state of semiflexion at elbows, wrists, and fingers, and trembled excessively when she tried to use them. They could not be extended, nor could the patient make use of the hands. She had been obliged to give up work on that account. Whenever she talked her face became painfully drawn and distorted. The mouth would especially be drawn downward. Under the least excitement she would be seized with what she called "choking spells." The throat muscles would contract and interfere seriously with respiration. She had constant headache, chiefly in the forehead and occiput, and a persistent pain in the neck. No painful points existed, nor did pressure, movement, or other tests reveal the existence of organic disease of the spinal cord. Sensibility to touch, pain, and temperature was normal. Motility was unimpaired. The muscular sense was perfect. No inco-ordination existed. I considered the case one of aggravated chorea, complicated by headache and asthenopia.

*Treatment and Results.*—The muscular anomalies were satisfactorily relieved by graduated tenotomies of both internal recti and the left superior rectus. Applications of static sparks were made daily for about two months. The patient had by this time regained the use of both hands, carried her head erect, had no headaches, and little spinal pain. For a while she returned to work. The effect of hard labor brought back her "choking spells"; hence she was advised to take a year of absolute rest. She now has some asthenopia remaining and an occasional headache. Her facial contortions persist to a slight extent when she is unduly excited. I suspect that some latent hyperphoria exists still, and that further operative work on

the eye muscles will be demanded before the patient recovers completely.

*CASE XVI. Constant Headache for Sixteen Years, associated with Nervous Prostration that kept her in Bed for Five Months.*—Mrs. A., wife of a physician, aged thirty-three. Has had two children.

*Family History.*—Mother has headache. One sister has headache. Two sisters have poor eyes. One paternal aunt died of phthisis.

*Eye Defects.*—At the first examination the patient showed the following condition: O. D. + 0.50 s. C + 0.50 c. axis, 90°. O. S. + 0.50 s. Right hyperphoria, 2°. Exophoria, 1/3°. Adduction, 37°. Abduction, 10°. Right sursumduction, 8°. Left sursumduction, 4°. Later, under atropine, the refractive condition was slightly modified—*i. e.*, O. D. + 1.00 s. C + 0.75 c. axis, 115°. O. S. + 1.50 s.

Glasses were ordered for constant wear as follows: O. D. + 0.50 s. C + 0.75 c. axis, 115. O. S. + 1.00 s.

After wearing the glasses for three days there was no apparent muscular defect, the hyperphoria having disappeared. Adduction, 39°. Abduction, 8°. Right sursumduction, 6°. Left sursumduction, 5°. No hyperphoria. No exophoria.

*History of the Case.*—The patient began to have headache at seventeen years of age. About eight years ago she began to have more severe headache, which now has become constant, with exacerbations about every two weeks and also during menstruation. About five years ago she picked out a pair of glasses (+ 0.50 s.) for herself which helped her somewhat at first. She had been under the care of a prominent gynecologist for retroversion, but without improvement in her headache. The pain is in the left temporal region, running both backward and forward. For five months she was confined to her bed with headache, and her husband (a physician) thought she had organic trouble. She has tried all drugs, electricity, etc., without benefit.

For years she has only been able to walk short distances with the aid of her husband's arm.

*Treatment and Results.*—The treatment consisted simply in ordering the glasses for constant wear to correct her error of focus.

The result of wearing the glasses was almost magical. Within a week she reported that she had walked four miles, was up till 2 A. M. at an entertainment, and had had no headache; that she felt better than for nine years.

In a letter received from her husband three months later, he says: "I am very glad to say to you that Mrs. A. has improved very much physically and mentally since you fitted her with glasses. She has not had a particle of the old headache, with but one exception. The time I speak of was at her menstrual epoch, and then but slight and only for a short time."

*CASE XVII. Chronic Chorea followed by a Loss of Power in both Legs and the Right Arm.*—Miss S., female, aged ten. A large child for her age.

*Family History.*—Mother is perfectly well. Father has had some eye trouble. One cousin on maternal side had epilepsy. One maternal aunt has nervous prostration. Paternal grandmother has nervous prostration. Considerable phthisis in the father's family.

*Eye Defects.*—Latent hypermetropia, + 1.00 s. Esophoria, 8°. Adduction, 38°. Abduction, 2°. Right sursumduction, 2°. Left sursumduction, 2°.

*History of the Case.*—The patient has had several severe sicknesses from acute diseases.

Eight months ago it was noticed that she could not keep her hands still and was constantly knocking things over. This kept growing worse until, six weeks before she came to me, she lost

all use of the right hand. Her ankles, which had been weak for some time, turned over so badly that she occasionally fell down. At times her speech was badly affected, and her words often ran together so as to be almost unintelligible. When she reads, the letters blur badly and her eyes become very much inflamed. Her eyes had troubled her for some time before any choreic symptoms were noticed. One eminent neurologist of this city had seen the patient and pronounced the case as one of organic brain disease.

*Treatment and Results.*—The treatment consisted in giving 2° of prism, base out, over each eye for constant wear, and later in graduated tenotomies of both internal recti.

The improvement in the choreic symptoms began almost as soon as the prisms were put on. At the end of the first week her mother reported that she could dress herself much better than formerly; that her right hand rested quietly in her own when walking, whereas it used to be impossible to hold it on account of the twitching. She also began to use her right hand for the first time to denote the position of candles while being tested.

The patient now, four months after treatment was begun, writes and sews with her right hand, walks perfectly well, without turning of the ankles, and has no choreic symptoms whatever. The power in her right arm has been fully regained. The parents state that "she is as well as she ever was," and express the greatest gratitude because of her restoration to health.

CASE XVIII. *Constant Headache, suspected to be a Symptom of Tubercular Meningitis.*—Miss B., female, aged ten; a large child for her age.

*Family History.*—Father and mother both had headaches when young. Several cases of phthisis on maternal side. Patient has three sisters and one brother, all healthy.

*Eye Defects.*—At the first examination the patient showed a myopic astigmatism (− 0.75 c. axis 180°) in both eyes. Later, under atropine, there was found hypermetropia (+ 0.75 s.) and hypermetropic astigmatism (+ 0.75 c., axis 90°) in both eyes.

Her muscular condition, with her refraction corrected, was: Esophoria, 2°; no hyperphoria; adduction, 36°; abduction, 7°; right sursumduction, 2°; left sursumduction, 2°. One eye shows a decided tendency toward convergent squint.

*History of Case.*—In August, 1890, this little patient began to suffer with severe headache, which soon became almost constant. She was treated for malaria and other diseases by drugs, but with no improvement in her head. She was taken by the family physician to two prominent oculists in this city for examination, and both prescribed astigmatic glasses, which gave slight but temporary relief. As the headache again returned with great severity, the glasses were taken off by one of the oculists, and her mother was told by him "that the child probably had tubercular meningitis."

When she was brought to me the headache was almost constant, and so severe at times that she could neither eat nor sleep, and was steadily losing in weight. Three years ago she had a fall on her head, and had slight evidence of cerebral concussion. She has suffered with severe nose-bleed, especially when her headache is severe.

*Treatment and Results.*—Almost a full correction of her refractive error was given for constant wear—*i. e.*, + 0.50 s. ◯ + 0.75 c., axis 90°; and one degree of prism, base out, was added over each eye to correct the esophoria.

The patient reports that she has only had one slight headache since she put on the glasses four months ago. Her mother says that she "has never seen her child so exuberant in spirits, and she has never been so well since she was first taken ill in

August, 1890. She has no pain, her appetite is good, and she is perfectly well."

The clinical history and treatment of the preceding cases have been given with as full detail as a brochure will admit of; yet I have deemed it wise also to tabulate the more important points in order that the reader may be able to contrast them and note the details of each case.

If by the histories of these cases the fact is not established beyond cavil that "eye-strain" was a cause of the symptoms reported, and that its correction brought about a marked amelioration of the symptoms (if not a cure), then I shall lose faith in the value of evidence to medical minds in a scientific medical inquiry.

Personally, as a neurologist, I meet in my office (as do others in the same field) two types of cases:

(a) Those who have *organic brain* or *spinal-cord diseases*, and to whom little hope of eventual recovery can be honestly extended. Rest from care, massage, electrical treatment, diet, exercise, and drugs may prolong life and decrease suffering in these cases; but nothing can restore to them perfect health, because destructive processes in the nerve-structures have permanently impaired some part of the nervous mechanism.

(b) The second type of cases encountered comprises those whose sufferings may be equally acute (if not more so) as those of the former class; but in whom *no positive evidence of organic disease can be discovered* by any step known to medical science.

Among the latter class we meet hundreds where we encounter one of the former. We are appealed to by the victims of chronic or periodical headaches, neuralgias, sleeplessness, nervous prostration (with its endless variety of symptoms), St. Vitus's dance, some cases of epilepsy, and many of deranged mental functions, for relief that drugs, electricity, massage, etc., have failed to give.

It is absurd for any one to argue that in such cases as those reported in this brochure the recognized therapeutical agents have probably been injudiciously administered by physicians in attendance; or that, on the other hand, the existence of some organic disease must account for the persistency of the symptoms. It is begging the question for any medical man to assert that organic disease exists simply because drugs fail to arrest symptoms.

Case No. I, reported in this article, demonstrates most positively, I think, that the most serious prognosis was apparently justified by the symptoms; yet they were in this case arrested at once through a simple surgical step. How many more cases of a similar character may exist to-day with the exciting cause unrecognized? How many may have gone to their graves with the cause undetermined?

So it is, only perhaps to a somewhat less startling degree, with other cases reported in this paper. They all point with the strongest emphasis to the importance of *investigating the eyes and eye muscles of every patient with chronic functional nervous affections.*

Some of these cases had been examined by oculists who failed to detect the eye defects that existed; hence it is fair

to presume that the latest methods of examination for defective equilibrium in the eye muscles were not employed by the oculists in question.

In bringing this brochure to a close, I would advance the following conclusions as demonstrated by the facts here reported.

Case.	Sex.	Age.	Symptoms.	Duration.	Former treatment.	Previous diagnoses.	EYE TESTS.		Eyc treatment.	Results.
							Refractive errors.	Muscular errors.		
1	Male.	41	Complete mental and physical collapse. Insomnia. Severe neuralgic attacks.	1 year. 6 months. 30 years.	Medicinal, massage, water treatment, electricity, diet, etc.	Organic cerebral softening (by several physicians).	O. D. } +0.50 s. } +0.75 c., ax. 90° O. S. } +1.25 s. } +0.50 c., ax. 90°	Left hyperphoria, 4°. Esophoria, 7°.	Spherical and cylindrical glasses. Graduated tenotomy of left sup. rectus. Graduated tenotomy of right internal rectus.	A practical cure. Patient still has some headache, but has entirely regained his mind and is able to resume control of his finances. The insomnia and neuralgia have ceased.
2	Male.	19	Epilepsy. Epileptic mania.	5 years. 2 years.	Enormous doses of bromides, with chloral, arsenic, and other drugs, without any relief.	Epileptic mania (papers were drawn to commit the patient to an asylum as an incurable).	No defect in either eye, even when under full effects of atropine.	Esophoria (mostly latent). Right hyperphoria (entirely latent at first visit).	Wearing of prismatic glasses. Graduated tenotomy of right sup. rectus. Graduated tenotomy of each internus.	One attack during past two years. Patient has taken no drugs for nearly four years, and has entirely regained his mental and physical strength. Both had been seriously affected by the bromides in the past.
3	Male.	43	Epilepsy.	24 years.	Enormous doses of bromides for many years without benefit, cerebral galvanism, massage.	Epilepsy (from early masturbation and later sexual excesses).	Hypermetropia. O. D. } +2.50 s. O. S. } +2.50 s. (Entirely latent, and therefore unsuspected by the patient.)	Esophoria (mostly latent).	Full correction of the hypermetropia by spherical glasses. Graduated tenotomies upon both interni.	An apparent cure. Patient taken no drugs and has had no seizures for nearly six years.
4	Male.	35	Epilepsy	Unknown.	Unknown.	Epilepsy.	O. D. } +1.50 s. } -2.75 c., ax. 180° O. S. } +1.50 s. } -2.75 c., ax. 180°	Esophoria, 4°.	Spherical and cylindrical glasses only.	An apparent cure. Patient has not had a fit since April, 1890.
5	Male.	26	Epilepsy. An approach to mental imbecility from bromides.	6 years. Since bromides were begun.	Bromides in very large doses, causing serious mental sluggishness and apathy.	Epilepsy. This patient had seen many physicians of eminence and none had disagreed on the diagnosis.	O. D. } +0.50 c., ax. 90° O. S. } +4.00 c., ax. 180° } -1.00 c., ax. 90°	Esophoria, 11°.	Correction by spherical and cylindrical glasses. Graduated tenotomies upon both interni.	Patient has not had a fit for eighteen months. Has taken no drugs. Has regained his intellect and gone into business pursuits. Travels without an attendant and weighs eighteen pounds more than when eye treatment was begun.
6	Female.	21	Complete nervous prostration. Constant pain in head. Inability to walk.	5 years. 5 years. 5 years.	Electricity, massage, drugs of all kinds.	Organic spinal and brain disease (by several physicians).	O. D. +1.25 s. Hypermetropia.	Left hyperphoria, 2°. Exophoria, 2°.	Spherical glasses. Graduated tenotomies upon both externi and left superior rectus.	Patient is now teaching gymnastics in a ladies' school.
7	Female.	42	Nervous prostration. Trembling of face and limbs. Neuralgic attacks of a violent form.	10 years. 8 years. 16 years.	Electricity, massage, drugs of all kinds, ertine treatment.	Organic disease had been strongly suspected. This patient had employed physicians by the score and had received no benefits from drugs.	Emmetropia. (No defect, even under atropine.)	Esophoria, 3°. (A much higher degree of latent esophoria disclosed itself later).	Graduated tenotomies upon both interni.	This patient had never suspected any eye trouble; but made a perfect recovery within a month after the last tenotomy was performed. Five years have elapsed without a return of a single symptom. For over sixteen years she had been a hopeless invalid.
8	Female.	42	Great despondency. Confusion of mind and thought. Loss of emotional control. Confirmed sleeplessness. Constant headache.	1 year. 1 year. 1 year. 1 year. 1 year.	Had consulted an oculist who "found nothing wrong in the eyes." Had been under care of a specialist who prescribed drugs, electricity, and restricted diet, with only partial and temporary benefit. Had never used glasses, even for reading or sewing.	Organic brain disease had been suspected. One physician "feared the approach of melancholia." Undoubted symptoms of insanity had appeared at times.	Hypermetropia. O. D. +0.75 s. O. S. +1.25 s. (Under atropine.) Prosyopia. Spherical glasses (+2.50) tolerated well for reading, sewing, etc.	Esophoria, 7°. Right hyperphoria, 2°.	Spherical glasses for distance. Strong reading glasses. Graduated tenotomies upon both interni and right superior rectus muscle.	This patient was enabled to resume her profession, and was restored to health without the use of drugs until within a week of her death. The full history of this case is of special interest.
9	Male.	23	Melancholia. Morbid impulses. Severe neuralgia (of bladder and prostate gland).	1 year. 1 year. 8 months.	This patient had been treated for months by a specialist for prostatic disease. He had also taken drugs of all kinds for his mental condition.	Cerebral congestion. Organic brain disease had been suspected.	Hypermetropia. O. D. +2.50 s. O. S. +2.50 s. (Entirely latent and unsuspected by patient.)	Esophoria, 12°.	Spherical glasses for constant wear. Graduated tenotomies upon both interni.	Complete cure. The patient is restored to mental and physical health, and has resumed his profession. All neuralgic attacks have ceased for past five years.
10	Male.	46	Nervous prostration. Sleeplessness. Pain in head.	15 years. 15 years. 15 years.	This patient had been under constant medical care. Drugs gave no benefits or relief.	Cerebral congestion. Excessive business cares.	Hypermetropia. O. D. +1.00 s. O. S. +1.00 s.	Esophoria, 13°.	Graduated tenotomies upon both interni.	Complete recovery. During the past two years this patient has had no return of his former symptoms.

Case.	Sex.	Age.	Symptoms.	Duration.	Former treatment.	Previous diagnoses.	EYE TESTS.		Eye treatment.	Results.
							Refractive errors.	Muscular errors.		
11	Female.	45	Complete nervous prostration. Chronic bladder trouble. Chronic sleeplessness.	1 year. 5 years. 1 year.	Patient had been confined in bed for about one year from nervous collapse. Drugs of all kinds had been administered without permanent benefit. Uterine treatment had accomplished nothing.	Some obscure form of abdominal disease had been suspected by the many physicians who had seen her in consultation.	Hypermetropia. O. D. +1.75. O. S. +1.75. Presbyopia. +4.50 s. needed for reading or sewing.	Right hyperphoria, 3°. Esophoria, 7°.	Spherical glasses for distance, and stronger ones for reading or sewing. Graduated tenotomies upon both internal recti and the right superior rectus muscle.	This patient has been able to walk for miles and to take full charge of her house since the tenotomies were performed (two years and a half ago). She has taken no drugs, sleeps well, and is apparently restored to perfect health.
12	Male.	23	Chronic neuralgia. Asthenopia. Headaches.	10 years. 5 years. 10 years.	Drugs of all kinds without beneficial results. Patient had contemplated suicide.	Some local disease was suspected as the exciting cause of the neuralgic paroxysms.	Hypermetropia. O. D. +2.00 s. O. S. +2.00 s.	Esophoria, 6°.	Spherical glasses for distance, and stronger ones for reading. Graduated tenotomies upon both internal recti muscles.	Complete cure. (No neuralgia for past two years.)
13	Female.	40	Nervous prostration. Confirmed digestive troubles. Inability to walk or endure fatigues.	6 years. Most of her life. 6 years.	Uterine treatment for years. Drugs of all kinds. "Rest cure" (for 3 consecutive months). Electricity for months. Massage.	The uterine trouble was always supposed to be the chief cause of the physical weakness.	Hypermetropia. O. D. +1.50 s. O. S. +1.50 s.	Esophoria, 4°.	Spherical glasses for reading, sewing, etc. Graduated tenotomy upon the left internal rectus muscle.	Complete cure for past six years. This patient can walk for miles, and her digestive functions are perfect.
14	Female.	45	Nervous prostration. Abnormally large pupil in one eye. Confirmed sleeplessness.	Several years. 12 years. 1 year.	Had taken drugs of all kinds. Had consulted a prominent oculist without benefit. The wife of a prominent medical lecturer and practitioner.	The diagnosis in this case had been very obscure to all that had been called to examine this patient	Hypermetropia. Astigmatism. O. D. +0.50 s. C. +0.50 c., ax. 75° O. S. +1.50 s. C. +0.50 c., ax. 105°	Apparent orthophoria.	Spherical and cylindrical glasses for constant wear were alone prescribed.	A very rapid recovery of strength, and a return of the pupils to equal size. Almost complete relief of the insomnia.
15	Female.	26	Chronic chorea. Aggravated deformity of head and limbs. Headache. Asthenopia.	16 years. 4 years. 16 years. 16 years.	This patient had been seen by many physicians. Drugs and electricity had accomplished nothing.	Organic spinal disease had been suspected.	Hypermetropia. O. D. +0.75 s. O. S. +0.75 s.	Esophoria, 20° (mostly latent). Left hyperphoria, 3°.	Graduated tenotomies upon both interni and left superior rectus muscle.	Relief of the deformity of the head and neck, and marked amelioration of the other symptoms. The patient was enabled to return to her former position, and has since been self-supporting.
16	Female.	33	Constant headache. Nervous prostration.	16 years. 5 months.	Has been under uterine treatment without relief. Has taken drugs, electricity, massage, etc., without benefit.	Organic disease had been suspected.	Hypermetropia. Astigmatism. O. D. +1.00 s. O. S. +0.75 c., ax. 115° O. S. +1.50 s.	Orthophoria.	Spherical and cylindrical glasses to fully correct all latent errors of refraction.	Rapid and complete cure. The patient walked four miles in less than a week. No return of headache for past two years.
17	Female.	10	Chronic chorea. Loss of power in right arm and both legs.	8 months. 6 weeks.	Drugs of all kinds.	Organic brain disease (by an eminent neurologist of New York)	Hypermetropia. O. D. +1.00 s. O. S. +1.00 s.	Esophoria, 8°.	Graduated tenotomies upon both interni. Prismatic glasses for some months prior to tenotomies.	Complete restoration of power to the limbs, and disappearance of all choreic movements.
18	Female.	10	Constant headache (very severe). Steady decrease in weight.	14 months. 14 months.	Drugs. Rest from school. Country air. Had been examined by two noted oculists.	One oculist told the parents that the "child probably had tubercular meningitis."	Hypermetropia. Astigmatism. O. D. +0.75 s. O. S. +0.75 c., ax. 90°	Esophoria, 2°.	Cylindrical and spherical glasses, combined with prisms for the esophoria.	Immediate cessation of all headache, that has not since returned. This patient is now perfectly well.

CONCLUSIONS.

1. "Eye-strain" may be said to exist *whenever errors of refraction or a maladjustment of the tendons that move the eyeballs in unison with each other can be demonstrated.* The extent and type of the errors found modify in each individual the relative amount of this strain and its probable significance as a factor in influencing the physical state.

2. The *determination of refraction without the use of atropine is unscientific,* and usually unreliable as a matter of record.

3. The variety and extent of errors of adjustment of the ocular tendons *can not be positively determined without a phorometer and the judicious use of prisms.* Neither is one

test, or even a series of tests, necessarily conclusive in some complex ocular problems.

4. The tests for the detection of maladjustment of ocular tendons are of *little or no value until the errors of refraction are detected and rectified* by proper glasses—accurately centered to the pupils.

5. The methods employed in public institutions (to save time and trouble) of determining refraction by an ophthalmoscope are unreliable and unscientific. *Javal's instrument is a better one;* but even this instrument ought to be used with a pupil widely dilated with atropine, and its results confirmed by other tests commonly employed to detect astigmatism.

6. The condemnation of any method by those who have not perfected themselves by personal practice with its details has no bearing upon a scientific inquiry.

7. The conditions that cause eye-strain (see conclusion 1) are usually congenital; hence they are seldom the result of any debilitated physical state.

8. "Eye-strain" is a frequent cause and perhaps the most important of all factors that tend to produce functional nervous diseases. This is demonstrated, I think, quite clearly by the cases reported, which embrace examples of most of the functional nervous affections in an aggravated form.

9. Statistics drawn from the records of public charitable institutions, where large numbers of patients are examined, are of little or no value in this particular inquiry. The tests and records are usually made in such institutions with haste and without proper regard to the methods that should be employed to make them more than approximately reliable. It is almost impossible to do accurate work under these conditions. Few public institutions possess the necessary apparatus, or use it if they have it.

10. I have yet to encounter a case where typical sick headaches occur that is not associated with "eye-strain." Latent hypermetropia exists to a marked degree in most subjects that are so afflicted, and esophoria is also frequently present.

11. The table which accompanies this article shows at a glance (what, in my experience, is the rule) that esophoria, hyperphoria, and hypermetropia are the most common abnormal eye conditions encountered in cases of neuralgia, headache, epilepsy, chorea, insanity, nervous prostration, and other severe types of chronic nervous disturbances. Exophoria and myopia are far less frequently encountered among these subjects.

12. Hypermetropia is much less frequently corrected among sufferers than myopia, although it is by far the more important eye defect in nervous diseases. The condition of hypermetropia may exist to a very high degree and be totally unsuspected by the patient. It may even be undetected by an oculist until atropine is employed to fully dilate the pupil and arrest the action of the focusing muscle (ciliary action).

13. A typical "cross-eye," although a deformity, is not, as a rule, the cause of serious nervous disturbance. These subjects have habitual "double vision" in consequence of their eye defect; hence, since no effort on the part of the patient can result in the fusion of the images of the two eyes, the patient learns early to suppress one visual image and to use only one eye at a time for visual purposes. For that reason, "eye-strain" is practically absent in extremely "cross-eyed" subjects.

14. Respecting the relationship of chorea to anomalies of the visual apparatus, I would draw the following conclusions:

a. Choreic subjects belong to one of two classes: (1) Those who tend to get well under almost any treatment or even without treatment, and (2) those who fail to get relief from any medicinal aid. The latter tend to run a chronic course, usually one of unfavorable progression.

b. The chronic form of chorea is one of the most serious and hopeless of nervous maladies. It is not infrequently associated with epilepsy or with mental impairment.

c. Both forms of chorea are based, as a rule, upon a well-marked neuropathic or tubercular predisposition.

d. The pathology of chorea is not known. No one has ever proved that it was a "constitutional disease," in the sense that an organic lesion was essential to its development.

15. The accurate fitting of frames to the face of each patient is a factor too often overlooked in attempts to relieve "eye-strain." A glass not accurately centered to the pupil may cause great distress, and frames that allow the axis of either glass to be tilted so that they sit at an angle before one or both eyes cause a strain in themselves, as the glasses then act like prisms before the eyes.

I have seen many instances where serious nervous disturbances have been modified almost immediately by simply changing the frames of the glasses that the patient had previously worn.

156 MADISON AVENUE.

#### MANAGEMENT OF THE NEW-BORN INFANT.\*

BY FLOYD M. CRANDALL, M. D.,

NEW YORK.

THE subject of this paper, lying as it does on the borderline between two departments of medicine—obstetrics and pædiatrics—has, as a natural result, received very inadequate attention. Most works on diseases of children contain no reference whatever to the management of the healthy newborn infant, and but slight attention is given to the numerous ailments and disorders of the first two weeks of life. Works on obstetrics, while they contain numerous scattered references to the infant, are chiefly concerned with the mother and rarely give connected instructions upon the important matters pertaining to the child. It is a frequent complaint that mothers and nurses follow the physician's directions regarding medicine, but pay no heed to his instructions concerning diet and the details of management. This is usually the doctor's own fault, for while he gives definite orders regarding treatment, his instructions regarding management are vague and indefinite, chiefly because his ideas are vague and indefinite. Clear-cut and definite directions upon any subject will usually be followed faithfully, especially if written.

As my professional experience has been to a considerable degree in these two departments, my attention has been frequently called to the improper treatment which the infant frequently receives. I have ventured to present it to-night, therefore, not because there is anything new or remarkable to offer, but because it is a subject of interest to the general practitioner which is seldom discussed in a connected and compact manner. It has seemed almost impossible for writers who have attempted the subject to

\* Read before the Society of the Alumni of Bellevue Hospital, February 3, 1892.

confine themselves to their text. In an article upon the new-born infant, recently published in a series of monographs, the writer passes from tying the cord to dentition, both temporary and permanent. This paper is restricted to conditions arising during the first fifteen or twenty days of life.

During the progress of labor the interests of the child are to be considered in various ways. General discussion on the use of the forceps is not within the province of this paper. To the child I am convinced that they are less dangerous than ergot. Ergot babies are blue babies, and the more the ergot the bluer the baby. A physician, living in a locality where public opinion is intolerant of instruments, who has had considerable experience with ergot, recently expressed to me very strongly the same opinion. From a study of a considerable number of birth-palsies I have been led to the belief that forceps are a less potent factor in their production than prolonged and tedious labor. There seems to me little room for doubt that instruments in the hands of a reasonably judicious man are less dangerous to the child than the continued compression of the head attendant upon labor prolonged in the second stage, or a prolonged first stage, when the waters have broken.

The vaginal douche before delivery is also a matter of importance as regards the child. With ordinary precautions it can do no harm, and may save much trouble. A vaginal discharge, even when apparently simple, may be the cause of ophthalmia, and is sometimes the source of serious general septic infection of the child. The douche should certainly not be omitted when the slightest purulent discharge is present, and should be repeated at intervals sufficiently short to insure cleanliness of the parturient canal.

Asphyxia may be the result of premature separation of the placenta, certain morbid conditions of the mother, weakness of the child sufficient to prevent respiratory action and expansion of the lungs, or obstruction of the respiratory passages by some foreign substance, but the most common cause is doubtless long-continued compression of the head. When not due to actual organic lesion of the brain it appears under two general forms. In one the head is blue and turgid, the face puffed and swollen, the lips are livid, while the body is of a lighter hue. The heart may usually be heard beating, and sometimes can be felt by the hand, the rate being usually slow. Under these conditions the possibility of resuscitation is good. If, on the other hand, the surface is pale and shrunken, the limbs flaccid, and the muscles without tone, the prognosis is bad, and whatever is done must be done quickly. Fortunately, the infant tolerates the condition of cyanosis better than the adult, probably from the comparatively low grade of oxidation to which the blood has been accustomed. As long as cardiac pulsations can be detected by auscultation, efforts at resuscitation should not be abandoned. If the child fails to breathe, the throat should be cleared of mucus by the finger, when one or two slaps upon the back or a sprinkling of cold water are usually sufficient to induce respiratory movements. If this fails, the application of alcohol or whisky to the chest

may prove efficacious. If the child still fails to breathe, inflation of the chest by means of a catheter passed through the glottis is often effectual, and for this purpose the Mercier catheter, with its peculiar elbow, is admirably adapted. We are told that attempts to force air into the lungs without elevation of the epiglottis are futile. Practically, I have had better results by forcibly blowing into the mouth of the child, a thin handkerchief being spread over the lips and the nostrils being compressed, than by Sylvester's method of artificial respiration. Perhaps the air all goes into the stomach, but I certainly know that I have seen respiratory movements induced by the procedure. As I have thrown the head well back, the œsophagus may have been sufficiently compressed between the vertebrae and larynx to prevent the entrance of air into the stomach. The child is apt to be so relaxed and flabby that little or no expansion of the chest is gained by Sylvester's method. Marked results sometimes follow the alternate dipping of the child into hot and cold water, as described by Playfair. It is a great mistake to allow the child to lie unprotected from cold. If it is evident that prolonged efforts are to be required, the child should be placed in a bath of warm water and not removed until respiration is established. This maintenance of the vital heat, it seems to me, is a matter of the utmost importance.

I have recently in a single case had a satisfactory result by the method of inflation described last year by Dr. Forrest. The child is placed in hot water and the head is thrown backward so as to throw the vertebrae of the neck forward. The hands are drawn up and pressed against the sides. This compresses the œsophagus between the larynx and vertebrae, and at the same time the mouth opens. The physician then strongly blows into the mouth of the child. The head is then thrown forward and the arms are brought down to the side so as to compress the air from the lungs. The point of importance is the compression of the œsophagus, preventing the entrance of air into the stomach.

Under normal conditions, when the child is born the eyes should receive the first attention. They should be carefully washed with a boric-acid solution before the cord is tied. I have never abandoned the old Emergency Hospital practice in this regard, and have never regretted the slight trouble it costs. It is very easy to order a saturated solution of boric acid, or to carry a little powder from which a solution may be quickly made. It is placed in a cup with a small, soft handkerchief, or a few squares of cloth ready for use.

I now rarely use nitrate of silver. According to Credé's method, a drop of a two-per-cent. solution (ten grains to the ounce) is placed in each eye. The reaction is often severe and, as a routine practice, seems to me entirely unnecessary. In case of purulent vaginal discharge it should invariably be employed, but, as a rule, thorough use of the boric solution is sufficient. The satisfaction of having no ophthalmia to deal with would repay much more trouble than these simple measures cost. The necessity for prompt action when ophthalmia is present, and the method of treatment by silver, cold, and perfect cleanliness, is too well known to require comment.

While there is no necessity for undue haste in tying the cord, it is best to do so as soon as the eyes have been bathed. I have tried different lengths and have found a cord of about an inch and a half most satisfactory. I have also tried various forms of dressing, and have found nothing more satisfactory than the time-honored square of soft cloth cut in the center. Charred cloth, although recently commended by a high authority, in this day of antiseptics is a relic of barbarism. Cotton is better than linen, and should be rendered antiseptic by being soaked in a sublimate solution and dried. As the fluid of the cord exudes rapidly during the first few days, the dressing becomes damp, and should be changed every day. There is no need whatever of odor about the cord, and there will be none if it is kept clean and dry with powder, which for this purpose should contain salicylic acid. It will leave a better navel surface and will fall quicker, the average time being about the fifth day. The scar should be healed by the tenth day. With wet dressings, falling of the cord is usually later. The same is true with oily dressings, which some prefer. They are less cleanly and permit more odor.

The scar should be kept clean, and be dressed with the same powder. If a so-called umbilical polypus forms, it should be removed by means of a tight ligature. Smaller masses of granulation should be cut down with nitrate of silver and dressed antiseptically. The antiseptic care of the umbilicus can not be too strongly insisted upon. Simple moist antiseptic dressings or, still better, antiseptic powders are preferable to ointments.

The various diseases at and about the umbilicus are extremely rare when proper antiseptic treatment has been carried out. They require active surgical treatment and are beyond the scope of this paper. Tetanus neonatorum, now known to be of microbic origin, is, happily, a rare disease in this city, and will probably never occur under strict antiseptic management of the umbilicus and of abrasions upon the child's body.

The radical changes which take place at birth should not be forgotten. The child is suddenly transferred from an unvarying temperature of 100° F., where surface evaporation is impossible, to a varying temperature twenty degrees to forty degrees lower, where evaporation from surface and lungs is constant, and where it must rely wholly upon heat generated within its own body. It is wonderful that such a change is as well tolerated as it is. We should certainly do nothing to reduce the vital forces, and should take every precaution for preserving the vital heat. The child should be removed from exposure as soon as possible and wrapped in a warm flannel blanket.

It is best not to put the baby into the bath-tub at first. The *vernix caseosa* is soluble in fat, which should be employed for its removal. An animal oil is best, and every nurse will tell you that lard removes it more readily than any other substance. After thoroughly anointing every portion of the body, especially the folds and creases, the oil should be wiped away with a soft towel, a sponge, with a little warm water and soap, being used in places. On the following day, when the child has become more accustomed to its new surroundings, a more thorough bath may be

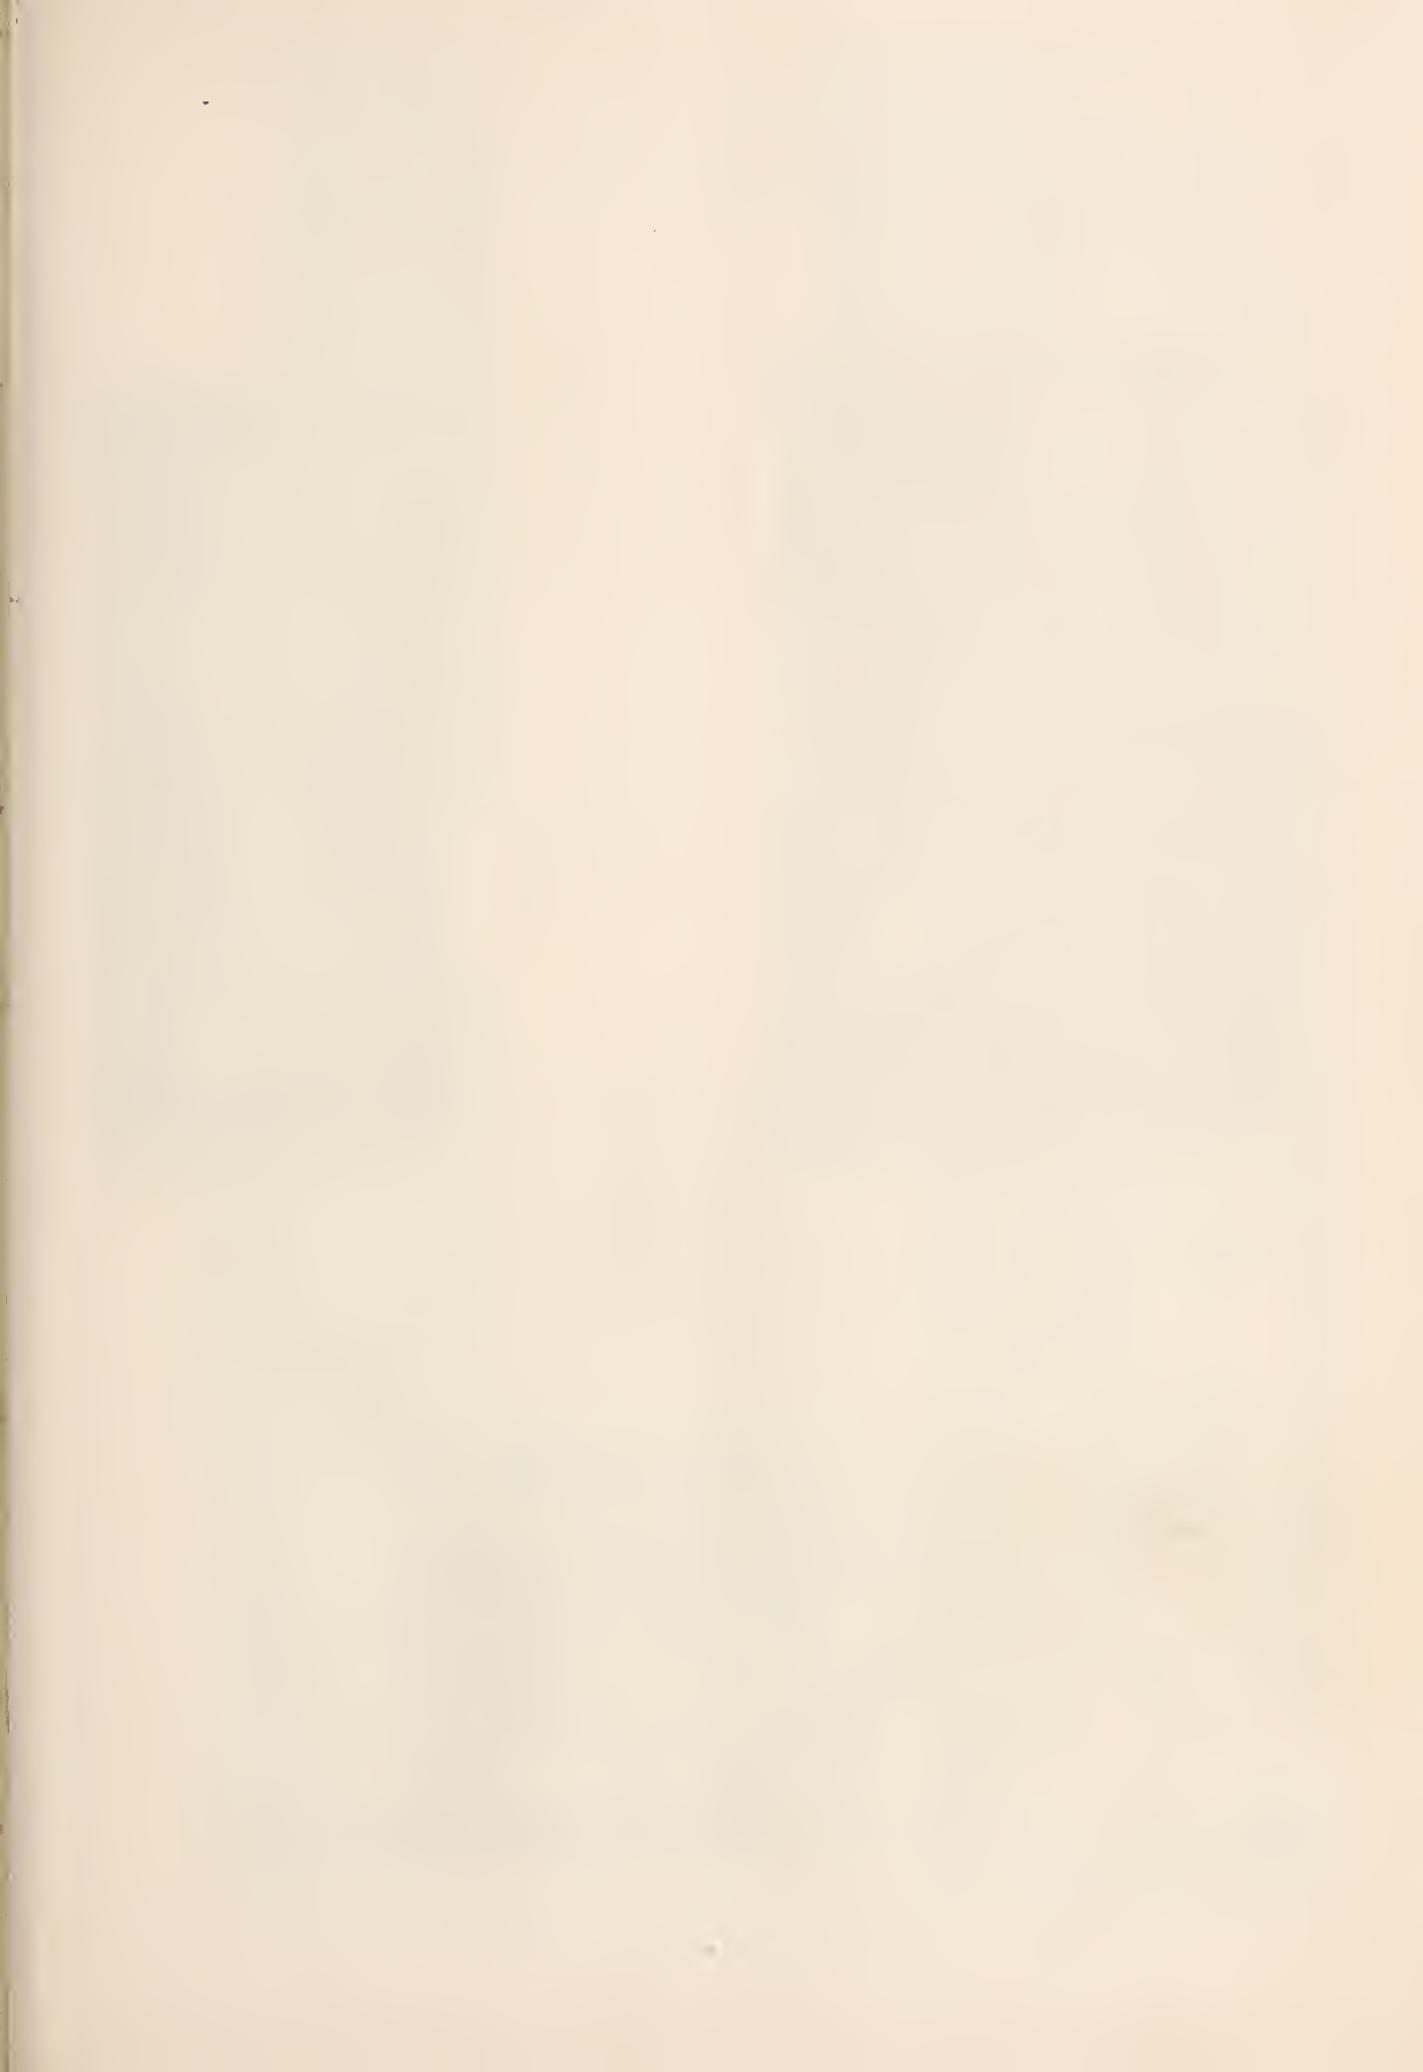

given, but it is best not to use the tub until the cord has fallen.

Absolute cleanliness throughout the whole period of infancy is of the most vital importance to the well-being of the child. The daily bath should be omitted only for the most serious reasons. The use of powder is a necessity, but is often overdone, the nurse depending upon it rather than upon care in drying the surface. Some powders are irritating and cause eruptions. Rice powder does nicely; starch is often improperly prepared; lycopodium is all that some skins will bear, and it may be advantageously added to most powders. If there is excoriation, two per cent. of salicylic acid or five per cent. of boric acid may be added. Salicylic acid is especially adapted to such use, and in some conditions, as for the cord, may be employed in the strength of twenty per cent. to eighty per cent. of starch. For ordinary purposes the compound talcum powder has been the most satisfactory preparation I have used.

The napkins should be changed as soon as soiled, even if it is every hour, and the child should not only be dried, but washed with water. Some nurses dry the napkins and use again without washing. Erythema is almost certain to follow such practice. In treating this disorder, it is best to question upon these points, and also as to the method of washing the napkins. If washed with strong soda or harsh soaps, without thorough rinsing, they will irritate the skin when wet and prolong the disorder, which is at best rebellious to treatment.

The parts should be very gently washed with water and perhaps a little borax, but no soap. If mild, a dusting powder containing salicylic acid or oxide of zinc may be used. If there is excoriation or much discharge, the powder may form into little masses and irritate. On the whole, I have obtained the best results from an oily preparation, which may not only be curative, but protects from discharges. The following, proposed by Fox, has been very satisfactory: ℞ Acidi salicylici, gr. x; bismuthi subnitrat̄is, ʒ ij; corn starch, ʒ jss.; ung. aq. rosæ, ad ʒ j. M. In some cases boric acid, or zinc oxide, in ointment with resorcin, seems to be more efficacious.

Before the child is dressed it should be inspected by the physician, and any birth mark or abnormality had better be reported to the father or some friend. Nurses are inclined to make capital upon such matters at the expense of the physician, using a discovery of some abnormality as proof of their superior knowledge of infants. The average male child, according to Dr. Smith's observation, weighs seven pounds eleven ounces; the average female, seven pounds four ounces. During the first three days there is usually a loss of weight, which has been regained before the end of the week. If the child does well, it should gain an ounce a day to three months, the original weight being doubled at six months and trebled at one year. The average length is nineteen inches, which is doubled at four years. The temperature at birth is 100°, which soon falls to 98.6°, and then returns to 99°. The pulse is about 130, which may be increased twenty or thirty beats by crying, or decreased ten or fifteen beats during sleep. Even in perfect health the pulse is often irregular and is practically

of no value as a symptom. The respirations are about 44, and fall to 30 at one year. The eyes are almost invariably of a greenish or bluish-gray color, and no opinion can be formed at birth as to what their permanent color will be. The pupils are large and sensitive to light. The auditory canal, owing to swelling of the mucous membrane, is usually closed, and there may be a slight discharge which might mislead the unwary. The abdomen, owing to the frequency of digestive disorders in infants, is an important region. The peculiarities in the relations of the abdominal organs are due chiefly to the great size of the liver, which displaces the stomach and colon to the left, the cæcum being extremely variable in position. The sigmoid flexure is long, sometimes reaching well into the right iliac fossa, and is the cause in some instances of persistent constipation. The bladder is almost wholly an abdominal organ, and its detection above the pubes does not necessarily mean undue distention.

While the physician is rarely consulted regarding the clothing of the infant, it is a subject upon which he should have some knowledge. Tight bands and waists are fortunately being superseded by more rational methods of dressing, though but slowly. The unfortunate infant is bound about the chest and waist by layer after layer, while the arms, legs, and neck have but half the covering. Each layer has its own array of buttons and safety-pins always at the back. The baby protests, and a new reef is taken in his bandages, already too tight, and he is put back in the cradle to lie on the same buttons, safety-pins, and lumps he has been complaining of. The Gertrude suit, of which so much has been said in *Babyhood*, is a vast improvement over old methods. The original suit has been considerably modified and improved, and does away with the bands and waists and all constriction about the body.

The band for the baby as well as for the mother is a disputed point. I can see no real objection when properly applied, but several advantages in a light flannel band during the first few months. It should be four inches wide, without a hem, and long enough to go once and a half about the body. Pieces of tape fastened to one end make a better fastening than pins. The shirt should be cut high in the neck and have long sleeves. Flannel should be used, for it is a necessity in this climate. The Jaeger flannel is by all means the best. It is rare that it can not be worn next the skin. In hot weather flannel should still be used, the thinnest possible being employed. The napkins are usually too thick and bungling. Soft cotton cloth is the best material. They should be cut a yard long and half a yard wide and folded once so as to make two thicknesses, the napkin when ready for use being eighteen inches square. If thicker and larger they are uncomfortable and may distort or deform the child. Rubber napkins and shields are objectionable from their tendency to overheat the parts. They are only admissible for short periods or when traveling.

The stockings should be long enough to fasten to the napkin and should always be kept on the feet. The outer garments, one of which should be of flannel, should not be so long and heavy as to obstruct the limbs. All the clothes should be opened in front.

I need not here urge the importance of breast feeding, but would urge more careful attention to the numerous details in the care and management of the breasts, neglect of which deprives many children of the food to which they are justly due. The breasts should receive attention at least six weeks before the birth of the child. Cracking of the nipples is to a large degree a preventable misfortune. The most efficient preventive measure is the gentle drawing out and manipulation of the nipple night and morning for several weeks before the beginning of lactation. Certain medicinal applications may be made with advantage at the same time. The usual application of astringents frequently fails utterly. I have seen a primipara who had faithfully applied solutions of alum, borax, and alcohol for two months obliged to stop nursing entirely on the fifth day because of deep fissuring of the nipples. They were certainly tough—as tough as sole-leather; and, like sole-leather, when pinched, bent, and squeezed, they cracked. They were not pliable; but pliability is as necessary as toughness. It is to be gained by frequent manipulation and the use of an oil. The best oil in my experience is lanolin, with a little cold cream added (one part to three) to render it less waxy and more readily applicable. It should be gently and thoroughly applied after each application of the astringent to counteract its tendency to stiffen and harden.

Both the nipple and the mouth of the infant should be washed with plain cool water, to which a few drops of listerine may be added, before and after each nursing. Decomposing milk on the nipple excoriates and favors fissuring; in the mouth of the child it irritates and forms a culture medium for bacteria. Without this care germs and spores which have lodged on the nipple and in the mouth are carried into the stomach during nursing and may develop serious digestive disorders.

Fissures, when they occur, try the physician's resources to the utmost. Not to enumerate the scores of drugs that have been proposed, I would simply say that on the whole I have had the most satisfactory results from the use of dry tannic acid. The nipple is cleansed with boric-acid solution and dried and the tannin dusted well into the fissures. It should be repeated after each nursing. It forms a coating that does not readily come off, and relief is usually experienced at the next nursing. The nipple should be afforded all the rest possible, and a shield should be used if practicable.

Sometimes, in addition to the fissures, or even when no fissure can be detected, the whole nipple becomes eroded and extremely sensitive. For this condition balsam of Peru is very effectual, or a one-per-cent. ointment of resorcin. In other cases there is a hypersensitiveness far out of proportion to the apparent seriousness of the fissures or erosion. The mother falls into an extreme nervous condition, and looks ahead with apprehension to every nursing. I saw a marked case of this character last year. The mother was anxious to nurse her child, but would fall into such a condition of nervous excitement before every nursing that bottle-feeding seemed inevitable. An application of a four-per-cent. solution of cocaine on a piece of cotton for five minutes was finally tried, and relieved the pain. The inter-

vals of nursing were extended as far as possible, and the cocaine used each time. The nipples were washed before and after each nursing and balsam of Peru applied. The mother was reassured, the strength of the cocaine was reduced, and in a week she was nursing the child without serious discomfort, and continued to do so during the summer.

For various reasons, nursing should be discontinued from a breast in which pus has formed or is forming. In mastitis, or any condition accompanied by fever, the constitutional disturbance alone often renders nursing impossible.

Unless the mother is especially exhausted, the child may be put to the breast at the end of four or five hours. During the first two days six hours is a sufficiently short interval for nursing. The child will get all the breasts contain, and will obtain no more by more frequent attempts. I can not say that I never give anything but the breast during the first two or three days. The child gets very little from the breast during the second day, and the stomach must become empty. A baby will wail and cry and show every evidence of hunger, and will drop quietly to sleep upon receiving a little warm fluid. If it is restless and crying on the second day, you may be quite sure that the nurse will give it something before night—it may be milk, broth, gruel, syrup, or sugar. It is better for the physician to prescribe what shall be given.

I have seen no bad results from weak oatmeal water. You thus give water that has been boiled, with sufficient nourishment to satisfy the scruples of the mother and nurse. But let the nurse feed indiscriminately with the score of things that tradition demands, and you will find about the fourth day that the family has been awake with a crying child. The bowels are usually loose, the passages being of bad odor, and perhaps greenish. With a mild laxative and exclusive breast feeding, the symptoms usually disappear in a few days, but the baby is subject to attacks of colic for a much longer time, and may have formed the pleasant habit of lying awake and crying at night.

Sometimes, I believe quite frequently, the mother's milk is too rich in fat during the first two or three weeks, causing colic, indigestion, and irregular bowels. Order outdoor exercise for the mother, increase the amount of fluid she takes and decrease the meat, for proteids in the mother's diet increase the fat in the milk. Give the baby a teaspoonful or two of Vichy water before each nursing, and the indigestion will probably disappear.

The most important matter in this whole subject of breast-feeding is regularity. It is even more important than in bottle-feeding, for the breast milk changes decidedly according to the frequency of nursing. If the interval is too long, it becomes thin and watery; if too short, concentrated and rich and causes indigestion. The first week is not too early to begin the formation of regular habits. If the child is asleep, wake it when the time for nursing arrives. It will soon form the habit of waking at regular intervals, and will go to sleep as soon as the nursing is finished. Above all things, warn the mother against continuous and everlasting night nursing. It wears on the

mother, impairs the milk, and ruins the digestion of the child.

A discussion of the subject of artificial feeding would occupy far more space than this paper will permit. To state the matter briefly, I would feed a child of average weight half an ounce of food every four hours during the first two days, soon increasing to an ounce every two hours, and an ounce and a half at the end of the second week. With one feeding between eleven at night and seven in the morning the child receives ten feedings a day during the first three months. As to the composition of the food, let it be cow's milk by all means. Allow the milk to stand in a bottle or pitcher for two hours and pour off the upper half. For the first feedings take of this rich milk four parts, lime water one part, and water seven parts. After a few days the milk may be increased and the water decreased. In warm weather the milk should be sterilized.

Urine is usually passed during the first twelve hours, and thereafter about an ounce is passed ten or twelve times a day, ten ounces being the normal average amount for the new-born infant. It is at first cloudy from the admixture of epithelial cells and uric acid and of very low gravity (1.003 to 1.006). Later it becomes clearer and pale, but the gravity continues low during childhood. When the urine does not pass, the distended bladder may be readily felt, as it lies very high. Usually hot applications over the hypogastrium, a sprinkling of cold water, or a warm bath are sufficient to start the flow. The catheter is very rarely required, and should be used only as the last resort.

The bowels usually act within a few hours after birth, the passages during the first two days, and sometimes longer, being greenish-black in color and tarry in consistency. If there is no passage, a teaspoonful of sweet oil is often sufficient, to which a few drops of castor oil may be added. In certain cases constipation is obstinate and persistent, and is due to an excessively long sigmoid flexure. In such cases a daily enema may be required until the child is several months old. Constipation is occasionally present from the first, the passages being hard and dry; more frequently it is acquired.

The treatment is often discouraging. The attention must be directed first and chiefly to the milk which the child receives, whether it is cow's milk or breast milk, and any error in digestion should be corrected as far as possible. Give plenty of cool water. This, I believe, is very important, for the infant usually requires more fluid than it obtains in the milk. Instruct the nurse to gently massage the abdomen daily, not by simply rubbing the surface, but by grasping the abdominal wall with the flattened hand and causing it to move upon the bowels beneath. If these measures fail, try a small soap suppository at the same time every day, or in more extreme cases part of a small-sized glycerin suppository, or half a teaspoonful of pure glycerin by syringe. Drugs should be the last resort. Among these, cascara has, on the whole, served me best, but sometimes fails completely. Two drops of cascara cordial may be given twice a day as the initial dose, to be increased if

necessary. When the passages are white or pasty and the child does not thrive, a few grains of phosphate of soda, given three times a day, often yield most satisfactory results. It may be added to the milk if the child is bottle-fed. Whatever drug is given, an attempt should be made to reduce the dose very slowly, relying more on diet and other measures. Mild measures at first are often sufficient, but if the bowels are neglected during the first few weeks a habit of constipation may develop which will be very hard to break.

Two errors are common in the treatment of chronic constipation. The first is reliance on a single measure—a single article of diet, a single mechanical measure, or a single drug. No one of these is of itself sufficient if the case is obstinate. The diet must be corrected and the attack must be made from several points at once. The second error is the attempt to cure a continuous and persistent condition by intermittent and spasmodic treatment. No matter how good the treatment, it is sure to fail unless persistently applied.

Jaundice in the infant, as in the adult, is symptomatic of numerous conditions. In the vast majority of cases it appears on the second or third day without assignable cause, continues about a week, and is unaccompanied by symptoms. The sclerotic is not discolored, the urine does not stain, and the stools retain their normal color. In rare instances acute obstructive jaundice marked by the usual symptoms occurs during the first week. The cause of the disorder has not been satisfactorily explained. There may be truth in the theory of Quincke, which attributes it to non-closure of the ductus venosus, which permits portal blood containing bile pigment to pass at once into the general circulation. As the condition naturally disappears, it rarely requires treatment. The clothing should be investigated, but it is extremely doubtful if bands could be so tight as to cause mechanical congestion of the liver. If the bowels are not free, gray powder is, perhaps, the most appropriate cathartic.

Thrush is a disease of young infants and marasmic children. It is rarely seen in healthy children when proper cleanliness of the mouth and nipples has been maintained, for it does not develop on a perfectly healthy membrane. Digestive disorders, while common in connection with thrush, are not necessarily a part of that disease, but result more from the swallowing of acrid secretions than from actual extension of the thrush. It is best combated by an alkaline wash. Borax is a time-honored remedy, and a good one. I have seen better results by adding to the mixture an equal amount of bicarbonate of sodium. Honey or syrup should not be used as a vehicle, for their decomposition adds to the disease. A simple solution in water is best, to which a little glycerin and tincture of myrrh may be added. Gentle but thorough removal of the exudation should be practiced three times a day by means of a soft cloth saturated with the solution, and wrapped on the finger or a lead-pencil. Unless this is done with extreme gentleness, more harm than good will result. If the disease is localized, the spots may be touched to advantage with a two-per-cent. solution of sulphate of copper.

Colic is most common between the second and fourth months, but not infrequently appears during the first week, and may be severe and very troublesome, the attacks being periodical, with a tendency to recur at the same time each day. The causes and preventive treatment have already been considered. It seems sometimes almost impossible to prevent it, and treatment for its relief is demanded. The feet will usually be found cold, and should be made warm at once. This simple precaution is sometimes followed by relief of the pain. Heat should also be applied to the abdomen, the warm hand of the nurse sometimes being sufficient. A little plain warm water may be given, to which peppermint may advantageously be added. Three or four drops of rhubarb and soda mixture in a teaspoonful of warm water is extremely effective. Aniseed cordial (elixir anisi) is frequently used, and is quite efficient. It contains twenty-five per cent. of deodorized alcohol. Dalby's carminative, so largely used, it should be remembered, as commonly dispensed, is an opium mixture of half the strength of paregoric. Equal parts of lime water and cinnamon water, or equal parts of camphor water and compound tincture of cardamom, are effective mixtures. The mother should never be allowed to suppose that she can use paregoric for these attacks. The temptation to overuse it is altogether too great.

So little is said of snuffles in the text-books, except as a symptom of syphilis, that many a young practitioner has been worried by a simple and very common disorder. Cold in the head is common in infants, and is more serious than in older children. Frequently it amounts only to snuffling or rattling, and perhaps sneezing without much closure of the passages. It can not become very severe, however, without preventing nursing by obstructing the breathing, and this is the serious aspect of the disorder.

Syphilitic coryza begins with a watery, somewhat acrid discharge which soon becomes muco-purulent, is frequently streaked with blood, and forms excoriations and thick scabs upon the lip. It persists and becomes steadily worse, and is rarely present for any length of time without other syphilitic manifestations. Simple coryza rarely continues longer than a week or ten days; the discharge is not as acrid, but frequently becomes so thick as to wholly occlude the nasal passages, which are comparatively small in the infant.

Treatment, when the disease is mild, consists in applying warm camphorated oil over the bridge of the nose and introducing a little cold cream into the nostrils with a camel's-hair brush. In more severe cases the nostrils must be as thoroughly cleaned as possible with a brush or piece of cotton wrapped on a probe, or an attempt may be made to gently syringe the nostrils with Seiler's solution, after which the cold cream may be applied. Gentleness here, as in treating diseases of the mouth, is of the first importance.

Bronchitis at this early age is an extremely serious disease, for if marked it virtually means broncho-pneumonia. The term used by some of the older writers—*suffocative catarrh*—expresses very well the clinical aspect which the disease is inclined to assume. Treatment does not differ materially from that of the same disease in older children.

Bronchitis is important also from another point of view.

In a recent study of congenital heart disease, I found that a large percentage of the cases suffered from bronchitis during the first week. The fetal openings of the heart and vessels do not fully close until the seventh or eighth day, and it has been suggested that bronchitis, by causing pulmonary obstruction, may be a factor in causing their continued patency. Every precaution should certainly be taken to prevent the disease, and it should be removed with the greatest possible dispatch.

Cerebral hæmorrhage, due to venous congestion and rupture of the capillaries of the pia mater; the various forms of obstetrical paralysis; hæmorrhages from the various cavities; trismus neonatorum—are all serious conditions of great interest, but their consideration is prohibited from lack of space.

Numerous minor ailments or abnormal conditions occur which require attention. Cephalæmatoma is a collection of blood commonly subperiosteal. It forms a tense, somewhat elastic tumor, situated, in the great majority of cases, over the right parietal bone. Unless evidence of suppuration appears, it should be left entirely alone, for it rarely happens that the blood is not absorbed.

Swelling of the breasts is sometimes marked and causes considerable discomfort. They should be simply protected from pressure. Sometimes warm camphorated oil very gently applied seems to give relief. If suppuration occurs, which is rarely the case, they should be treated like any abscess.

If vomiting of blood occurs, the breasts should be examined, for a surprisingly large amount of blood may flow from a fissured nipple. Congenital teeth are not, as a rule, attached to the bone and soon loosen and fall. They should be at once removed. Vaccination, unless there is some definite reason for haste, had better be postponed until the child is at least six months old. It does not "take" well before that age, and it may be necessary to repeat the operation several times.

The baby may be wailing and puny, with low vitality and apparently little hold on life; the asphyxia may be deep; the convulsions long and severe; the indigestion obstinate, and yet the case may not be necessarily hopeless. In no condition is the truism that while there is life there is hope more true than in that of early infancy. Vigorous and healthy children not infrequently develop from the most unpromising infants. Many a strong man is to-day engaged in the active affairs of life whose first days promised nothing but speedy death. While an infant breathes it is never wise to wholly abandon hope or to relax one's efforts.

113 WEST NINETY-FIFTH STREET.

The Death of Mr. Henry A. Riley occurred in New York on the 9th inst., of heart disease, from which he had long been a sufferer. Though a lawyer, he was well known to the medical profession by his contributions upon medical jurisprudence to this and other journals. For many years he had been a contributor to current literature, and for two years, having been compelled to abandon his professional and business pursuits, he had devoted his time largely to writing upon medical law. In this direction his work was unique, for he developed a field before unoccupied, being quite different from that of medical jurisprudence as that term is usually understood.

## A CASE OF TWIN EXTRA-UTERINE PREGNANCY.

ABORTION *PER VIAS NATURALES* AT THE FOURTEENTH WEEK.\*

By A. L. ROBINSON, M. D.,  
SEATTLE, WASH.

Mrs. F. K., aged twenty-seven, multipara, came under my care about the middle of January, 1892, while suffering with *la grippe*. After the acute symptoms had passed, but while still weak, morning sickness came on. She informed me that her last menstrual period had commenced on November 4, 1891. The vomiting soon became almost constant, and was but slightly modified by any of the numerous remedies employed, which included rectal feeding. Extreme prostration, insomnia, and incipient nephritis made abortion advisable, and the patient, her husband, and other members of the household were so informed. While this procedure was being discussed, the patient told me that for several days small blood-clots had been passing, but that free hæmorrhage had not occurred. On the following day, February 6, 1892, Dr. Montgomery Russell, of this city, was called in consultation, and the previous treatment and proposed operation were approved by him. Ether was administered, and, anæsthesia being obtained, the cervix was exposed and a protruding muco-blood-clot removed. An intense violet color of the vagina was observed. After dilating the cervical canal a careful examination of the uterine cavity was made. It measured five inches and a quarter from external os to fundus, and its contents were a few small blood-clots only. These were removed. A roughness was noticed at or near the right Fallopian uterine ostium. Dr. Russell's examination confirmed the results of mine. We concluded that the product of conception had died *in utero*, undergone maceration and partial absorption, and the remainder passed with the discharges previously mentioned, which had probably been greater in amount than the patient supposed. The uterine cavity was then syringed out with two quarts of a warm bichloride-of-mercury solution (1 to 3,000), and faradaic electricity applied for fifteen minutes.

That evening it occurred to me that the condition was possibly extra-uterine pregnancy. At my next visit the patient was closely questioned, and it was ascertained that for several weeks dull pains had been emanating from the right iliac fossa and extending downward on the thigh. An extremely offensive discharge from the vagina, which she supposed was leucorrhœa, had continued during this period. At first it was thick and viscid, but recently had become watery and mixed with small blood-clots. Since the cessation of menstruation her subjective symptoms had differed greatly from those of her two former pregnancies, but in what manner she could not clearly state.

An attempt was then made to make a bimanual examination of the pelvic viscera, but fear of pain caused so much protestation that it was not persisted in, for she was so weak and nervous that convulsions were feared. The employment of an anæsthetic was considered unsafe at that time. External palpation gave no positive results, as pressure was not tolerated.

The family was informed of my conjectures, and the various forms of extra-uterine pregnancy with their possible terminations were explained.

The day following the operation the attacks of vomiting decreased in frequency. Nausea and occasional vomiting persisted, consequently but little nourishment could be taken at one time. Rectal feeding, gastric and nerve sedatives, tonics and stimulants were employed, but the general condition was not greatly improved. Pains emanating from the right iliac fossa con-

\* Read before the Seattle Medical Society and Library Association, March 16, 1892.

tinued; also a slight discharge of blood from the uterus. The cavity of the latter was several times explored, the blood-clots found therein removed, and warm bichloride injections made.

On the evening of February 17, 1892, eleven days after first examining the uterus, I was sent for in haste. Considerable pains had been experienced all that afternoon, commencing in the right iliac fossa, but later extending to the sacrum and assuming the characteristics of labor pains. Previous to my arrival she had been delivered of an embryo with considerable hæmorrhage. The patient was too much prostrated to permit cleansing the uterus at that time, the pulse being 120 and weak, temperature 100° F. Hæmorrhage was checked by ergotin hypodermically, and brandy and digitalis were ordered. During my visit the following morning a second embryo was passed without pain. Hæmorrhage was inconsiderable. The uterus was at once everted and a large blood-clot and shreds of membrane removed, as well as small pieces of placenta, which were scraped with difficulty from the location of the right Falloppian uterine ostium. Its cavity was then syringed out with a warm bichloride solution and ergot prescribed.

Examination of the embryos showed them to be of about fourteen weeks' development. They were more than five inches in length, and had evidently been considerably compressed and elongated. The heads were shapeless masses. Membranous nails were forming on fingers and toes. The sexes were not distinguishable.

Hæmorrhage continued daily, at times requiring electricity, astringent and styptic injections, and the administration of ergot, but these measures failed to satisfactorily control it. Examinations of the uterine cavity were several times made, and its only contents, blood-clots, removed.

The patient continued weak, with continual nausea and frequent vomiting. Temperature varied from normal to 99.5° F., and pulse from 95 to 105 and weak. Pain was constantly complained of, mainly on right side of the uterus. Morphine, phenacetin, salol, and gelsemium were frequently administered to modify it.

Laparotomy for the removal of the placenta and membranes was considered, but neither at that time nor at any other was the patient strong enough to justify such an operation.

On February 23d she had a slight chill followed by rise of temperature to 102.5° F. The following morning the temperature was 102° F., pulse 130, respiration 30. The abdomen was considerably distended and tympanitic, severe pain was complained of, and vomiting was more frequent.

Dr. Russell was again called in consultation, and he concurred in my diagnosis of general peritonitis. Turpentine stupes were applied to the abdomen and the "Alonzo Clark opium treatment" was agreed upon and commenced, the patient being closely watched until her tolerance for the drug was ascertained. Respiration increased to 38 that day. The duration of this treatment was ninety hours; one hundred and forty-one grains and a half of pulverized opium were administered, and three grains and three eighths of sulphate of morphine given hypodermically to lessen vomiting. The acute symptoms gradually subsided, and on the evening of February 28th vomiting had not occurred for six hours, abdominal pain and tympanites had disappeared, temperature was normal, pulse 105, respiration 14. Opium was given that night at increasing intervals and then discontinued. On the morning of February 29th I found the patient with temperature of 100° F., pulse 125, respiration 20. The uterine cavity was explored, an entire placenta removed, and it was then syringed out with a warm bichloride solution.\*

\* A large piece of placenta had been removed from the uterus four days previously.

An enema of warm water and soap brought away considerable hardened clay-colored feces. Fifteen grains of sulphate of quinine and cardiac stimulants were given. A tablespoonful of a saturated solution of sulphate of magnesium was ordered every four hours. During the afternoon the temperature fell to 99° F., but the pulse increased in rapidity and feebleness. I remained by the patient's bedside all that night. At 4 A. M., March 1st, the pulse was 150. At 5.20 A. M., shortly after waking from an hour's sleep, death resulted from asthenia.

For some years palpitation of the heart and uncasiness in the cardiac region had at times been complained of. Much prostration had been caused by *la grippe*, and the vomiting of pregnancy following this disease so closely prevented the retention of the tonics and stimulants ordered. But for debility caused by *la grippe* it is believed the patient would have recovered.

Minor details of treatment, etc., have been omitted. It was undoubtedly an interstitial pregnancy on the right side, the growth of the embryos enlarging the Falloppian uterine ostium and permitting their entrance into the uterus. The shape of the uterine cavity, as disclosed by the several examinations, negatives the probability that this was a case of pregnancy in one portion of a uterus bicornis.

A post-mortem examination was not obtained.

Cases of extra-uterine pregnancy with delivery *per vias naturales* are extremely rare. Dr. Charles McBurney reported one in the *New York Medical Journal*, March number, 1878, page 273, and Dr. Cornelius Williams another in the same journal, December number, 1878, page 595, but an examination of the literature at my disposal fails to disclose a case of *multiple* extra-uterine pregnancy with that termination; indeed, I find no cases of *multiple* extra-uterine pregnancy of any variety, though possibly some are of record.

2506 JACKSON STREET, March 8, 1892.

## RECOVERY AFTER TAKING A LARGE QUANTITY OF VERATRUM VIRIDE.

BY JAMES P. TUTTLE, M. D.

MR. A. was attacked on February 5th with severe epididymitis and orchitis. That night his brother came to me, saying that his fever was very high and that he was suffering a great deal of pain. I prescribed for him "tr. verat. virid. (Norwood's), f ʒ iv. Sig.: Two drops every half-hour until perspiration is well established." The patient read the directions "two teaspoonfuls" every half-hour, and took the first dose accordingly at 8.30 P. M. This he retained without any appreciable effect until 9.05 P. M., when he took the second dose of two teaspoonfuls. In about half an hour he "began to vomit and became very weak," as he described himself. On the following morning I was called to see him, and having heard his story of how he took the medicine, was more surprised to find him alive than that he was exceedingly weak and very pale. The heart was feeble but regular, and the respiration very nearly normal. A small quantity of whisky and infusion of digitalis were given, and the patient recovered without any unusual symptoms. The prescription was compounded by a reputable pharmacist, who assured me that he had dispensed the stronger tincture. The interest in the case centers in the remarkable fact of the patient's having retained so large a quantity of the drug for nearly an hour without any disastrous effects.

THE  
NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 18, 1892.

OPIUM-SMOKING.

ACCORDING to an editorial note in the *Journal of the American Medical Association*, the vice of opium-smoking, or "*opiokapnism*," as the writer calls it, has been increasing to a remarkable extent during the last decade. The statistics of the custom-house at San Francisco show that the sum of \$750,000 was collected last year as the duty on importations of smoking-opium at that port alone, with the tariff at twelve dollars a pound. In other words, 62,000 pounds of a drug which has no good uses and has a bad history in other countries came into a single port of entry in one year. In addition to the openly imported drug, a very large illicit trade is carried on over the Canadian border. It is said that a million pounds of the smoking-drug has come into the country in eleven years through the port of San Francisco alone.

The term "*opiokapnism*" is used by the writer in contradistinction to "*opiophagism*" (or opium-eating), a term which has been coined to cover the commoner forms of addiction to opium or its derivatives in which the drug is taken by the mouth or by subcutaneous injection.

"*Opiophagism*" may be taken to represent those cases of the morphine habit which are so common in all parts of this country, being very frequent among professional and other refined persons, and concerning which the medical profession has so much of unjust blame laid to its charge as being the occasion of the formation of the habit. "*Opiokapnism*," on the other hand, is an Oriental and un-American vice. Introduced by the Chinese laundrymen, opium-smoking has spread somewhat in the depraved purlieus of our Western and Northern cities. This is the imported vice, the causation of which has not as yet been laid to the charge of our profession. The therapeutic indications of the smoke of opium are not regarded in the Orient as of any moment whatsoever, and it is not at all probable that any good uses will ever be discovered for it. In the article above cited, it is stated that fifty qualified native physicians of the city of Bombay have signed a statement that among their Hindoo patients the habit of smoking opium is an evil without a redeeming feature, ruinous alike to mind, body, estate, and family.

MINOR PARAGRAPHS.

THE CONSERVATIVE TREATMENT OF TUBAL DISEASE.

AT the last meeting of the Academy of Medicine, on Thursday evening of week before last, a notable paper on The Conservative Treatment of Salpingitis was read by Dr. Paul F. Mundé. The paper was remarkable for the clearness with which it showed

the absence of justification for what the author denominated the "Birmingham epidemic," meaning the rage for salpingo-oophorectomy. As he justly remarked, it is one of the drawbacks of the Listerian system that it has to a great extent robbed certain mutilating and unnecessary surgical procedures of their danger to life, and consequently led to their indiscriminate and often utterly uncalled-for execution. We have no hesitation in saying that among the most flagrant of them is laparotomy for disease of the Fallopian tubes, and we think the profession ought to feel thankful that a gynæcologist of Dr. Mundé's eminence has taken the trouble to demonstrate the rarity with which it is required. Dr. Mundé used the word conservative in the sense of *preservative* of the essential generative organs in women, and it is interesting to note that their preservation is not incompatible with a curative laparotomy, as was strikingly brought out in the discussion by Dr. Polk, who related briefly the history of a case in which he had removed the uterine anexa on one side for disease, and at the same operation had cut away about half of the ampulla of the oviduct on the other side, and yet the patient had since conceived. Surely such a case ought to rise up against those who lightly declare in cases of tubal disease that the organs have already been rendered functionally worthless by disease, and therefore that their loss by a surgical operation is really no loss to the patient.

A WORTHY SANITARY FEAT QUIETLY ACCOMPLISHED.

It is alleged for General Rusk that he has greatly improved the treatment of cattle exported to Europe for food purposes. The mortality among them at sea, resulting from cruelty, want of water, etc., was formerly stated at sixteen per cent., while at the present time it is one per cent. The value of these exportations is not far from \$25,000,000 annually. If this statement is only partly true, General Rusk has accomplished a great sanitary reform, for he has been the means of indirectly purifying the flesh-food supply of thousands of European consumers.

WOUNDS WITH DYNAMITE.

THE action of dynamite seems to be almost as chaotic as that of lightning, to judge from an occurrence related in *La Science moderne*, an abstract of which is given in a recent number of *L'Union médicale*. A nickel-miner was fishing with dynamite cartridges, when one of them exploded as he was in the act of casting it and carried away one of his hands. During the twelve hours that it took to convey him to a hospital ship, under a tropical sun, gangrene set in, and he died shortly after reaching his refuge. His body was riddled with communicating subcutaneous channels, and at the post-mortem examination it was found that the nails of the lost hand, having been detached, had acted as projectiles, and were found near the spinal column in the thoracic region.

ITEMS, ETC.

**The Medical Society of the County of Queens.**—The annual meeting of this society was held on May 31st, at Mineola, Long Island. The following officers were elected: President, Dr. C. J. G. Finn; vice-president, Dr. John Mann; secretary, Dr. James S. Cooley; censors, Dr. Meynen, Dr. Heyen, Dr. Ludlam, Dr. Frye, and Dr. Zabriskie. It was voted to elect delegates to the State society and to re-establish the broken delegate relations that have been interrupted since 1884. Dr. Cooley and Dr. Lanchart were elected such delegates. Delegates were also appointed to the American Medical Association. Dr. O. B. Douglas, of New York, and Dr. G. G. Hopkins, of Brooklyn, read papers at the meeting.

**The Medico-chirurgical College of Philadelphia.**—The following appointments have been made: Dr. W. Frank Haehtlen, professor of obstetrics; Dr. W. Easterly Ashton, professor of gynecology; Dr. Charles M. Seltzer, professor of hygiene; Dr. H. H. Boom, adjunct professor of chemistry; and Dr. B. T. Shimwell, adjunct professor of operative surgery.

**Bellevue Hospital.**—Dr. Robert W. Taylor has been appointed on the attending staff, on the division of the College of Physicians and Surgeons, to have a continuous service in genito-urinary diseases.

**The Woman's Medical College of the New York Infirmary.**—Dr. William Oliver Moore has resigned from the chair of ophthalmology and otology.

**The New York Polyclinic.**—Dr. Robert Safford Newton has been appointed lecturer on diseases of the mind and nervous system, in the department of Professor L. C. Gray.

**The Death of Professor Meynert.**—The *Lancet* announces the death of Professor Theodor Meynert, of Vienna.

**Change of Address.**—Dr. P. A. E. Boetzkes, to No. 861 Lexington Avenue.

**A Large Bequest for Hospital Purposes.**—By the will of the late Mr. Robert A. Barnes, of St. Louis, the sum of nine hundred thousand dollars will become available for the building and endowment of a new hospital in that city. The management of the fund will rest with the Methodist Episcopal Church South, but the institution, when completed, will be unsectarian in the bestowal of its charities.

**The late Dr. Birdsall.**—The New York Neurological Society has passed the following:

Inasmuch as by the death of Dr. William R. Birdsall, the New York Neurological Society has lost an active member, whose eminent services in our department of medicine have secured for him our highest respect, and whose many attractions of character and personality have awakened our warmest attachment; therefore,

*Resolved*, That we record upon our minutes the expression of our great sorrow at his untimely death; of our appreciation of his eminent ability, untiring industry, and scientific accuracy and skill; and of our tender regard for the many admirable qualities which will endear his memory to us for many years.

*Resolved*, That these resolutions be published in the current medical journals, and that a copy be sent as an expression of our deep sympathy to the afflicted family of our deceased friend.

[Signed.]

M. ALLEN STARR, M. D.,  
CHARLES L. DANA, M. D.,  
GRENE M. HAMMOND, M. D.,  
*Committee of the Council.*

#### Society Meetings for the Coming Week:

**MONDAY, June 20th:** American Association of Genito-urinary Surgeons (first day—Richfield Springs, N. Y.); American Ophthalmological Society (first day—New London, Conn.); New Hampshire Medical Society (first day—Concord); New York County Medical Association; Hartford, Conn., Medical Society; Chicago Medical Society.

**TUESDAY, June 21st:** Colorado State Medical Society (first day—Denver); American Association of Genito-urinary Surgeons (second day); American Ophthalmological Society (second day); New Hampshire Medical Society (second day); Medical Societies of the Counties of Kings and Westchester (annual), N. Y.; Ogdensburg, N. Y., Medical Association; Baltimore Academy of Medicine.

**WEDNESDAY, June 22d:** Colorado State Medical Society (second day); American Association of Genito-urinary Surgeons (third day); New York Pathological Society; Medical Society of the County of Albany; Metropolitan Medical Society (private); Philadelphia County Medical Society.

**THURSDAY, June 23d:** New York Orthopædic Society.

**FRIDAY, June 24th:** New York Society of German Physicians; Philadelphia Clinical Society; Philadelphia Laryngological Society.

**SATURDAY, June 25th:** New York Medical and Surgical Society (private).

#### Answers to Correspondents:

No. 383.—Their formulæ are probably of no special value. Ninety-five-per-cent. alcohol has been used with good results.

## Proceedings of Societies.

### AMERICAN MEDICAL ASSOCIATION.

*Forty-third Annual Meeting, held in Detroit on Tuesday, Wednesday, Thursday, and Friday, June 7, 8, 9, and 10, 1892.*

The President, Dr. HENRY O. MAROY, of Boston, in the Chair.

(Concluded from page 664.)

**Recommendations of Proprietary Medicines.**—A resolution from the Medical Society of Pennsylvania was read by the secretary, which disapproved of the common custom among physicians of giving certificates of the value of patent and proprietary medicines. The *Journal of the American Medical Association* was condemned for encouraging such practice in its advertising columns.

Dr. THOMAS, of Pennsylvania, offered a resolution that the trustees of the *Journal* be directed to abide by the code of ethics by declining to make commendatory mention of secret preparations. This resolution was unanimously adopted.

**The Pan-American Medical Congress.**—The PRESIDENT introduced Dr. WILLIAM PEPPER, of Pennsylvania, the president of the Pan-American Medical Congress. Dr. Pepper referred to the preparations for the Congress which had been made, and expressed the belief that the managers would do all in their power to make the Congress successful and beneficial.

Dr. C. A. L. REED, of Ohio, offered a resolution thanking Senator Sherman, of Ohio, for his efforts in securing the passage of the bill incorporating the Congress through the United States Senate, and expressing the hope that the bill would speedily be passed by the House of Representatives. This resolution was unanimously adopted.

The PRESIDENT announced as the Committee for Consideration of the Status of the Members of the Association belonging to the Medical Society of the State of New York and for Conference with Members of that Organization: Dr. Davis, of Illinois; Dr. Rauch, of Illinois; Dr. Briggs, of Tennessee; Dr. Reynolds, of Kentucky; and Dr. King, of Missouri; and, as a Committee on the Revision of the Code of Ethics: Dr. Didama, of New York; Dr. Lee, of Pennsylvania; Dr. Connor, of Michigan; Dr. Holton, of Vermont; and Dr. Nelson, of Illinois.

The reports of the treasurer and librarian were then read by the secretary.

The report of the Committee on the Rush Monument Fund was read by the chairman, Dr. A. L. Gihon, of the navy. An urgent appeal was made for contributions. The treasurer had already received nearly \$3,000, of which \$2,000 was securely invested. It was now positively decided that a monument would be erected in Washington, but whether it should be a bust or a full-length figure would depend upon the amount of money obtained.

**The Standard of Medical Education.**—Dr. DUDLEY, of Kentucky, read a preamble and resolution indorsing the action of certain American colleges of medicine in raising the standard of medical education, and urged that the colleges throughout the entire country be requested to adopt similar requirements. The preamble and resolution were unanimously adopted.

Dr. MILLARD, of Minnesota, moved that a copy of them be transmitted to every medical college and medical journal in the United States.

**The Report of the Committee on the Celebration of the Centennial of the Discovery of Vaccination** was read by the secretary. It recommended a celebration in the city of Washington, if possible, on May 14, 1896, when the centennial anniversary of Jenner's conclusive experiment in inoculation would occur; also that a committee of five be appointed to arrange a plan for such a celebration.

Dr. REYNOLDS, of Kentucky, asked that the nominating committee be requested to give its report upon the instructions that had been given to it.

Dr. WATSON, of New Jersey, replied that the report was not ready.

Dr. REYNOLDS moved that the committee be requested to render its report at Friday's meeting.

Dr. TRUAX, of New York, did not understand that the nominating committee had been called upon for a report, and called for the reading of the motions which were supposed to apply to the case.

Dr. QUIMBY, of New Jersey, did not consider that the nominating committee had any duty to perform in the matter at issue.

Dr. DAVIS, of Illinois, took the same view of the matter.

Dr. TONER, of the District of Columbia, said the minutes had been falsified by the introduction of names which had not been mentioned in the motions as offered upon the floor. This statement was strongly objected to by Dr. Gihon, of the navy. The president then declared further debate out of order.

**Intellectual Progress in Medicine.**—This was the title of the Address in Medicine, by Dr. A. L. GIBON. The reader did not propose to offer anything original, but would merely give a digest of the year's progress, which was to be found in the medical journals of the year—the search-light of medical progress. He called attention to the improved character of medical editorship, which, of course, had been required with increasing intelligence and aspirations on the part of the profession. It was only the highest ability that could now expect to reach the proper distinction in medical editorship. Reform in the system of medical education was also a most noteworthy fact. The lengthening of the period of education to three, four, and even six years, in addition to the required preliminary examination, which had obtained at numerous medical colleges, especially in the North and East, should be a stimulus to the colleges in the South and West which had not already adopted similar progressive measures. The duty of a physician in the line of education was to identify himself with educational medical societies, not only the county societies, but those of the State and nation as well. Thus would a physician become broader than by simply attending to his medical duties and his relations to his patients. The physician should also not forget his civil duties, and should ever seek to emulate such men as Benjamin Rush, who was not only physician and teacher, but patriot, statesman, and scientist as well. The action of medical men in founding and sustaining in recent years such organizations as the Loyal Legion and the Grand Army of the Republic was an evidence of the possibilities in this direction. The revelations of chemistry and bacteriology in recent times had been most interesting and valuable. Especially was it a comforting fact that, if many deadly microbes were in the body, processes were also at work within the body by which those microbes were destroyed. The old idea of the entity of diseases had long since been exploded and we now looked to modern science to explain upon a rational basis the morbid conditions with which we were everywhere confronted. The recent work of Sternberg on bacteriology was alluded to with pride as

a product of American medicine, and extensive quotations from that author's recent publications were made. He (Sternberg) believed that we were on the eve of a new era in the treatment of infectious disease, that the important question now was the isolation of the toxins and toxalbumins of the body, and that the inference was justifiable that in the blood and tissue juices of animals and human beings who had suffered with infectious disease antitoxines would be found which, by inoculation in the healthy, would render them proof against such infectious diseases.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of January 13, 1892.*

The President, Dr. ARPAD G. GERSTER, in the Chair.

**Injury of the Ulnar Nerve.**—Dr. McBURNEY showed a patient whose hand had been crushed eleven months before in a pane of glass. The ulnar nerve and artery and all the tendons on the anterior surface of the wrist were divided. Sensation on the ulnar side was completely lost. The artery was tied and the nerve and tendons were sutured. The result had not been satisfactory, on account of the adhesions of the tendons to the cicatrix. At a second operation the scar was freely dissected away from the tendons and nerve which were attached to it, all cicatricial tissue was removed, and the wound was sutured. The result was now eminently satisfactory; sensation was perfect and flexion practically normal.

**Nephrectomy.**—The PRESIDENT showed a woman, thirty-one years old, from whom he had removed one kidney while undoubted disease of the other was present. The tumor occupied the entire left side of the abdomen, and was very slightly movable. The patient's condition was wretched. The tumor contained pus, which was evacuated by the operation of nephrotomy, on March 3, 1890. Improvement took place, but, as elevations of the evening temperature still persisted and the discharge was profuse, it was decided to remove the kidney, which still formed a noticeable tumor. Nephrectomy was, therefore, done on January 23, 1891. A long oblique incision was employed between the last rib and the crest of the ilium. Extensive adhesions had to be torn, and the peritoneal cavity was freely opened. Several additional pus cavities were evacuated. The pedicle was secured by an elastic ligature, and the peritonæum by continuous suture was shut off. The wound was treated openly. The patient made an excellent recovery. The ligature came away on the thirteenth day. In four months the patient's weight had increased from ninety-nine to one hundred and thirty-five pounds, and she now enjoyed comparatively good health.

In another case he had done nephrectomy, with a satisfactory result, upon a patient whose other kidney at the time of operation was undoubtedly diseased.

Dr. LANGE remarked that he had operated in several cases where the second kidney was also diseased. The questions to be considered in such cases were: First, was the presence of the diseased kidney of such risk to the patient that its removal was desirable; and, secondly, was the kidney of use as a urino-secreting organ? In one of the speaker's cases the patient was still alive at the end of six years, and in another at the expiration of three years. Neither of them was cured, as the remaining kidney was not healthy, but both were living in comparative comfort.

The PRESIDENT said that an important point in the technique of such operations was the patient's posture. He used in such cases the posture suggested by Lange—*i. e.*, the patient lay on the side to be operated on, with the incision as low as possible, so that the pus might flow away from the peritoneal cavity.

**Cuneiform Osteotomy.**—The PRESIDENT showed two patients on whom he had done cuneiform osteotomy for cure of flat-foot. A semilunar incision was made on the inner side of the foot, an inch in front of and below the apex of the malleolus, and carried forward from two to two inches and a half. The wedge of bone was removed from the most prominent part of the foot without attention to the anatomical tissues, its base being on the inner margin of the sole and its apex on the outer side of the dorsum. He chiseled out the wedge piecemeal, rather than in one mass. The foot was then broken into shape, a plaster dressing was applied to the foot in its over-corrected posture, and the limb was kept elevated for a few hours. The first case was that of a waiter, aged twenty-two, who was operated upon on January 16, 1891. The result had been excellent. The second case was that of a man, aged sixty, and the result had been fairly satisfactory. Out of six cases of operation in this manner he had obtained a good result in five. No drainage-tubes were used, but the wound was left open at one angle. The bones removed were generally the head of the astragalus, the entire scaphoid, and part of the cuboid. He had found that in the simple Ogston operation not enough bone was removed.

### Book Notices.

*Diseases of the Nervous System.* By JEROME K. BAUDUY, M. D., LL. D., Professor of Diseases of the Mind and Nervous System and of Medical Jurisprudence, Missouri Medical College, St. Louis, etc. Second Edition. Philadelphia: J. B. Lippincott Co., 1892. Pp. 352. [Price, \$3.]

THE author states that the solicitations of his former pupils have induced him to prepare a second edition of a work that was published some sixteen years ago; and the same lack of proportion that then characterized the work is apparent in this rewritten edition. The title is misleading, for nervous diseases include much more than diseases of the brain and its membranes and those of the mind; and nowhere on the title-page is there an indication that this is a first volume in a series, as a sentence in the seventh paragraph of the preface suggests. Furthermore, if this was to be a comprehensive treatise, how could anatomical detail and physiological discussion be inadmissible, as the author states, notwithstanding the practical aim of the work? That he has not found this exclusion possible is shown in his first chapter, on the cerebral circulation. Besides the two cerebral pulsations mentioned on page 14 there is the third, the vascular wave, that is also a factor in affecting the intracranial pressure. One half of the nineteen pages in the first chapter is a quotation from Schroeder van der Kolk. And this is a feature of the volume, for we recall no book in which page after page of quotation is so often encountered as it is in this. And the quotation is not always correctly credited; for example, wherever M. Allen Starr's name is mentioned that of Frederick Peterson should be inserted, as he is the deservedly accredited author of the chapter on insanity in Dr. Starr's opusculum on nervous diseases.

Just as the author very properly objects to acute hydrocephalus as a nosological term, because it expresses one of the results of tubercular meningitis, so do we object to the exaggerated importance he attaches to cerebral hyperæmia and anæmia, which are merely general terms expressing the results of a variety of causes. And yet to these symptoms more space is devoted than to many more important conditions, such, for instance, as general paralysis.

In the chapter on meningitis, tumors and abscesses of the brain are not mentioned in connection with the diagnosis of that condition, and there is nothing in the volume regarding these not altogether rare diseases of the brain.

An entire lecture is devoted to the consideration of the comparatively rare condition of neo-membranes of the dura mater, while such diseases as chorea, hysteria, and paralysis agitans are not, or but barely, mentioned.

While, as a rule, the author's therapeutical recommendations are familiar, yet his prescriptions are examples of polypharmacy that one would not expect to see in a text-book of the day: one, for instance, calls for three varieties of pepsin.

In the effort to fortify his position by quoting he has too often obscured or eliminated the results of his own personal study and experience, thereby rendering the work unserviceable to the neurologist, while the unsystematic manner in which the subject is considered makes the volume one of the least useful to the medical student of any of the existing text-books on nervous diseases.

### BOOKS, ETC., RECEIVED.

*Traité de médecine.* Publié sous la direction de MM. Charcot, Professeur de clinique des maladies nerveuses à la Faculté de médecine de Paris; Bouchard, Professeur de pathologie générale à la Faculté de médecine de Paris, et Brissaud, Professeur agrégé à la Faculté de médecine de Paris. Par MM. Babinski, Ballet, Brault, Chantemesse, Charrin, Chauffard, Courtois-Suffit, Gilbert, Guinon, Legendre, Marfan, Marie, Mathieu, Netter, Oettinger, André Petit, Richardière, Roger, Ruault, Thibierge, Thoinot, Fernand Vidal. Tome III. Par MM. A. Ruault, A. Mathieu, Courtois-Suffit, A. Chauffard. Avec figures dans le texte. Paris: G. Masson, 1892. Pp. 987. [Prix, 20 francs.]

Proceedings of the New York Pathological Society for the Year 1891.

Medical Education and Legislation. By George J. Englemann, A. M., M. D., St. Louis, Mo. [Reprinted from the *Medical Fortnightly*.]

The Wills Eye Hospital, Philadelphia. Founded April 2, 1832. Reports for the Years ending December 31, 1890, and December 31, 1891.

Die Accumulatoren im Dienste der Medicin. Von Dr. W. Freudenthal, New York. [Separat-Abdruck aus der *Monatsschrift für Ohrenheilkunde*.]

Transactions of the Southern Surgical and Gynæcological Association. Volume IV. Fourth Session, held at Richmond, Va., November 10, 11, and 12, 1891.

Proceedings of the Philadelphia County Medical Society. Volume XII. Session of 1891. T. B. Schneideman, M. D., Editor.

The Purification of Water by Chemical Treatment. By Willis G. Tucker, M. D., Ph. D., Albany. [Reprinted from the *Albany Medical Annals*.]

D. Hayes Agnew, M. D., LL. D. Biographical Sketch by his Pupil, Friend, and Assistant, De Forest Willard, M. D. (Read by invitation before the Philadelphia County Medical Society, April 13, 1892.)

A View of Modern Surgery from the Standpoint of a General Practitioner. By James S. Green, M. D., of Elizabeth, N. J. President's Address, delivered before the New Jersey Medical Society, June, 1891.

The Use of Morphine and other Strong Sedatives in Gynæcological Practice. By Hunter Robb, M. D., Johns Hopkins Hospital, Baltimore. [Reprinted from the *Maryland Medical Journal*.]

The Bacteria in Wounds and Skin-stitches. By Hunter Robb, M. D., Baltimore. [Reprinted from the *Johns Hopkins Hospital Bulletin*.]

Les péricardites expérimentales et bactériques. Recherches du Dr. Alfredo Rubino. Résumé du Dr. G. Rummo.

Wichtige Gesundheitsregeln nicht bloss den Schülern sondern auch den Eltern und treuen Pflegern der Jugend in wohlmeinendster Absicht gewidmet. Von P. B. Sepp, kgl. Gymnasialprofessor. Zweite Auflage. Augsburg: Kransfelder'sche Buchhandlung, 1892.

Zwölf Vorlesungen über den Bau der nervösen Centralorgane. Für Aerzte und Studirende. Von Dr. Ludwig Edinger, Arzt in Frankfurt am Main. Dritte umgearbeitete Auflage. Mit 139 Abbildungen. Leipzig: F. C. W. Vogel, 1892. Pp. viii to 196.

## Miscellany.

**Medical Manhood and Methods of Professional Success.**—This was the title of a valedictory address delivered before the graduating class of the Marion-Sims College of Medicine, at St. Louis, on April 25th, by Dr. C. H. Hughes, professor of neurology, psychiatry, and electrotherapy.

To-night you conclude your curriculum and commence your life's career as physicians. But only your preparatory study ends to-night, not your pupilage. That must go on while you live. Thus far you have done well, and your *alma mater*, in recognition of your acquirements and appreciating your moral merits, has to-night bestowed upon you your well-earned laurels. For the past three years (and especially during the last eight months of your course) you have toiled faithfully, zealously, nobly; but if your study stops now, your energy fails, or your zeal ends here, the life before you will be an ignoble one, your work up to this hour will have been fruitless, and life a failure—not worth living.

I congratulate you on your auspicious entrance into the profession. You could not have decided upon a more opportune period in its history for efficient service to mankind or for satisfactory work to yourselves. This is the electric and dynamite age of the world—its time of greatest light and power. You enter the profession at an epoch of most remarkable advancement—an era of grand discovery and magnificent achievement for the glory and honor of medicine and the happiness of the race; a period when the microscope has achieved for medicine what the telescope has accomplished for astronomy, revealing in that grand cosmos of the infinitely minute beyond the reach of unaided human vision, myriads of hitherto unknown existences and laws of physiological and pathological motion; when chemistry has done her almost perfect work, and biology makes a pathway plain and clear through much of the *terra incognita* of the physiology of the recent past; and pathology, clinical medicine, and therapeutics have kept equal pace with the electric-light illumination that has so lately been thrown upon all physical science.

A new world of bacteriological and micrococcic life has been revealed to the pathologist, a new meaning has been given to the term microcosm by modern medical research. It means to the physician a great world of infinitely minute beings—microscopic pygmies in size and form, but giants in power to destroy, whose name is legion—the microcosm of the lens. When the history of this world beyond the ken of normal vision shall have been fully revealed, no fiction of Jules Verne will equal it in wondrous revelation. Many things, therefore, which the profession a generation or two before us saw but dimly and did imperfectly, we now see clearly and do with precision. The defective and incomplete methods of research and therapeutic resource of the fathers have given place to clearer vision in diagnosis and greater precision in practice. The endoscope, the test-tube, and the crucible of the chemist supplement this wondrous illumination of the way over which our ancestors groped in darkness. Antisepsis and the newer therapeutics have made dangerous pathways safe to the surgeon and averted the untoward endings of many formerly fatal diseases. They have made once painful surgical procedures painless and rendered many hitherto toxic processes harmless, while preventive medicine puts back the oncoming pestilence. Medicine, as it never stood before, now stands between the people and the pestilence, “and the plague is stayed.” The people dwell at home in security and flee no more from many of the scourges of the past, because our profession has found out methods to successfully combat them.

To you, gentlemen, belongs the proud honor of falling into line of battle with the Grand Army of Medicine while it is making this forward movement toward its grandest achievements. Foes fall before it that once appalled the profession and baffled its greatest chieftains. Other foes of human health and life are destined in your day (and perhaps yet in mine) to surrender to our blows for humanity's cause. The science and art of medicine all along the line are achieving wonderful victories for the welfare of mankind against the enemies of his health. In the glory

of this conquest of the closing century you are to be sharers—all of you if you will—and the names of some of you are destined, if you but will it so and work with a will to that end, to become renowned as those of great physicians and immortal human benefactors.

Lives of great men all remind us  
We may make our lives sublime,  
And departing, leave behind us  
Footprints on the sands of time.

I charge you then to

Be up and doing,  
With a heart for every fate.  
Still achieving, still pursuing,  
Learn to labor and to wait.

Yes, to labor and to wait. *Labor et patientia*. In this sign you shall conquer in the battle of life before you. In these and other lines of Longfellow's Psalm of Life we have the reminder of the example of the great before us for our emulation and advancement and of the influence of our own example in turn upon the lives of those who are to come after us in the profession; the fruition that follows faith, hope, courage—the stuff that all true men are made of—and fidelity to duty and conscience, without which no man can be a true physician.

They wove bright fables in the days of old,  
When Reason borrowed Fancy's painted wings,  
And Truth's clear river flowed o'er sands of gold  
And told in song its high and mystic things.

It is not so now. Though our ancestors in medicine saw many things as through a glass, darkly, and imagination sufficed and supplanted investigation, the modern physician is a student of fact and a diligent searcher after the unembellished truths of medical science, and these truths are “stranger than fiction.”

Hitzig's and Ferrier's cerebral localizations, Championnière's cranial topography, Macewen's and Horsley's surgical achievements, the autopsic verifications of others, and the spinal differentiations of Seguin and his colleagues, have given remarkable exactness to the topical diagnosis of brain and spinal-cord disease, so that neurology, with the aid of surgery, now locates and removes a blood-clot, spicula of bone or morbid growth, or empties a pus sac embarrassing, irritating, or paralyzing a speech, arm, leg, or other psycho-motor center in the brain; and the spinal cord may be penetrated in the same way for the relief of certain of its focal lesions, while deep-seated ganglia, like Gasser's, are cut out for the relief of intractable neuralgias.

Indeed, so great have been the recent advances in physio-anatomical knowledge of not long ago unknown localities and functions, and the perfection of surgical technique, that the timidity of some and the conservatism of others of the older surgeons in regard to operating within the cavities of the body has been replaced by an operative temerity that even now demands some repression in the light of clinical experience as to the sequences of certain surgical procedures. The annals of modern surgery in general give us records of unprecedented audacity with the knife. Scarcely any organ of the body escapes its saving or destructive touch. By a chemical process Senn searches for and sews up a severed bowel; Billroth exsects a stomach; German surgery extirpates a larynx and mechanical ingenuity replaces it with a pretty fair substitute. The lung has even been pared away under certain circumstances without causing the death of the patient, while hysterectomy, splenectomy, nephrectomy, oophorectomy, intestinal exsection, and the removal of the pelvic viscera generally are, some of them, common and others are not so frequent, but no longer impossible operations. So that the young graduate with surgical aspirations and eager for speedy fame has now rather to be cautioned as to when not to operate—cautioned to proceed with a conservative regard for his patients and to study and employ the milder means of relief before employing that last resort of the true physician, the total ablation of an important organ. In regard to all of these brilliant capital operations which some of you are or will be skilled and anxious to perform, I enjoin the golden rule, “Whatever you would that others should do unto you,” under similar circumstances, “do you even so to them.” No less, no more.

Virchow, Brown-Séquard, Charcot and Weir Mitchell, Hammond, Meynert, Nothnagel, Flechsig, Wernicke, Munk, Exner, and others, still diligently at work, have made, up to the present time, contributions to pathology, physiology, and neurological and clinical medicine generally, not before surpassed in the history of the profession's progress, while Pasteur, Formad, Tomassi-Crudelli, Laveran, Sternberg, Salisbury, Schmidt, and others have found the light in pathology and bacteriology for which our fathers hoped, but sought in vain.

Asiatic cholera and yellow fever are held at bay in their native lairs. The exact nature of that once deadly mystery, malaria, whose name confesses the ignorances of Watson and others of our not remote predecessors as to its real nature, is now known. Puerperal fever, eclampsia, and the autotoxic diseases generally are being unraveled. The pathological mysteries of phthisis, tetanus, diphtheria, etc., are solved. That *opprobrium medicorum* of the past—epilepsy—is now a manageable disease, and rheumatism has become almost as tractable as a common cold, if it were not for its unfortunate tendency to constantly recur. Skin and bone are now transplanted and made to grow on dermal soil once too barren for their sustenance, and arteries are ligated and intestines sutured with animal fiber. The abdominal and thoracic cavities are no longer forbidden ground to surgical interference. Laparotomy is triumphant. Penetrating wounds of these regions are no longer sealed and their unfortunate victims left to the tender mercies of fate and the *vis medicatrix naturee*.

You have been taught the nature and differentiation of nervous conditions, but it has not been long since to be nervous was to be simply indefinitely miserable to the physician, and grave neuropathic conditions which are now well known had no certain pathology and received no treatment.

Within comparatively a few years syringomyelia, acromegaly, exophthalmic goitre, poliomyelitis anterior, progressive muscular atrophy and its antipodal paralytic condition pseudo-hypertrophic muscular paralysis; posterior, lateral, anterior and postero-lateral spinal sclerosis, peripheral neuro-tabes, polyneuritis and the chronic toxic neuritides generally, athetosis, Landry's paralysis, bulbar paralysis, Friedreich's ataxia, paramyoclonus multiplex, morbus Thomsenii, paresis, paranoia, dipsomania, aphasia, Jacksonian epilepsy, polyneuritis, and too many other diseases of the nervous system—central and peripheral—to be here enumerated, have been diligently studied and accurately differentiated, evidencing astonishing activity in clinical and pathological investigation.

Cardiac, pulmonary, laryngeal, and cutaneous affections, surgical and gynecological diseases and those of the eye, ear, and every other organ, and many of the fevers are better defined and managed than they were even a few years ago, and scarcely any region or organ of the body is now exempt from surgical resource. Spencer Wells, Lawson Tait, and Marion Sims began their eminent careers and became famous for their work during the last third of this century.

Thus you see the past and the present have bequeathed to you a rich legacy of clinical and pathological knowledge, the accumulation of years of laborious research. What will you add to the scientific heritage? You certainly owe to your medical ancestry and to the world's posterity your best efforts to increase the store of fact you have so freely received.

The knowledge of the physiology of the almost omnipresent nervous and its attendant vascular system has so far advanced that we now appear to be fully familiar with the last factor in the phenomena of that wonderful discovery of the circulation whose initiative was made by Galen and Harvey—namely, that of the neural mechanisms of arteriole control through the vaso-motor and vaso-constrictor nerves. This added to the heart's propulsion, the *vis a tergo*, and the heart's exhaust, the *vis a fronte*, with what we know of the impressibility of the intracardiac ganglia of Ludwig, Remak, and Bidder, and of the regulating vagus and cardiac inhibitory nerve influence, gives to our knowledge of the circulation of the blood the appearance of the finality of a complete discovery.

New views of the function of the cerebellum in its relation to the cerebrum, at variance with the views of Flourens long accepted by the profession, have been advanced even pending your pupilage, notably those of Luciani, whose studies in the normal and pathological physi-

ology of this important organ I commend to your consideration. In fact, Luciani, as his accomplished reviewer, Seppilli, asserts, has destroyed Flourens's theory and assigned to the cerebellum trophic functions like those of the ganglia of the great sympathetic. The balancing power or equilibrating function of this organ seems, according to Luciani's exhaustive researches, to be secondary to cerebellar tonicity.

According to this eminent and most recent Italian investigator, three classes of phenomena characterize the healthy functioning of the cerebellum—viz., sthenic, tonic, and static neuro-muscular power—while damage to the cerebellum, sufficient to destroy its function, causes asthenic, atonic, and astatic neuro-muscular phenomena, and besides, his conclusions are in the direction of the functional unity of action of this organ, contrary to the views of Nothnagel. The theory of Flourens has been assailed in a different manner by Tolet, he giving to the cerebellum function of psychical sensibility.

How truly, then, can I cordially congratulate you, gentlemen, on the present auspicious beginning of your life work!

You have, by diligent industry and zealous endeavor, placed yourselves abreast of this wonderful progress the profession has been making, even some of it since you commenced your studies.

Omens of work already done give hopeful augury of a yet more victorious future. But you still have work before you, and much of it in contributing to unfold the yet unraveled mysteries of medicine. The present epidemic of influenza will claim your study, as it is engaging professional attention almost throughout the world, as a toxic neurosis, and the nature of the *grippe* toxine, as a poison of the nervous system, whether microbic or otherwise, is being closely investigated and will demand your attention. Even while I write, this subject is being elucidated by Babès, Pfeffer, and Canon, and some of you may make perfectly plain this and other unsolved problems to the final satisfaction of the scientific world. Why not? What man has done man may do. What graduates of other colleges have done the graduates of this school may do. Any of you may become great if you will, and be benefactors of your race and have your names enrolled high on the keystone of "Fame's triumphal arch." Mayhap some of you may be accounted by posterity as among the "few immortal names that were not born to die." At all events, it will not harm you if you strive for a place in history with the Türcks, Wallers, Hunters, Harveys, Ferriers, Jenners, Grosses, or Flints. Aim for the top even though you may not be able to climb beyond the middle rounds of the ladder of Fame.

The best calling in life is that which, after contributing sustenance to the worker, bestows the most good upon mankind. That calling is Medicine. It cares for the body of man and fits its tenant, the soul, for all the duties and demands of life. *Mens sana in corpore sano* is a maxim handed down to us from the ancient masters.

Without disparaging other professions or occupations, it can not be disputed that the practice and teaching of the medical art is the highest of benefactions. It is the greatest of charities as it is the noblest of human callings. The ministry of love was the life-work of the Divine Master, for though he began his mission as a carpenter and loved to dispute, as a boy, with the philosophers in the temple, he concluded his career as a physician of both body and soul, and went about healing the sick and doing good. He was the Great Physician.

The greatest and mightiest word that ever proceeded from the mouth of God or his apostles was "charity"—the fatherly love of God and the fraternal charity of man. St. Paul pronounced charity the highest of the virtues, and one of the sweetest-minded of the apostles was Luke, the good physician. The two professions that practice true charity more than all others are those of Medicine and Divinity, and in them the physician and the divine go hand in hand. There are no two of the callings of men so closely allied in their work. That true charity which considers in every aspect the welfare of our fellows, brings the doctor of divinity and the doctor of medicine close together. It was the appreciation of the true charity of our noble profession that caused Cicero to regard the physician as near the gods.\*

\* "Homines ad deos nulla re proprias accedunt quam salutem hominibus dando."

With the highest human sanction and the Divine example, I commend to you the practice of charity. It will do you good all the days of your life as well as those who may be the recipients of your ministrations.

It falleth like the gentle rain  
Upon the place beneath,  
And is twice blessed ;  
It blesseth him that gives  
And him that takes.

The study of the physician includes the moral as well as the physical well-being of man, for the purity of the soul has much to do with the health of the body. The purity of the heart and the dominance of the body by principles of rectitude has much to do with the health and consequent happiness of present and succeeding generations. The direct and hereditarily entailed diseases which are the offspring of sin, and *vice versa*, which have filled and are filling the land with misery and woe, both physician and divine are alike especially interested in preventing. The psychology of sin and the pathology of crime are studies alike for doctor and divine.

The man who is sick in his soul is seldom well in his body, and the soul's affairs do not prosper well when the body is disordered.

Like the divine, the physician may also aid in healing "the wounded in spirit and the broken-hearted," and in "binding up their wounds." He may "minister to a mind diseased," and "with sweet oblivion's antidote cleanse the stuffed bosom of that perilous stuff which weighs upon the heart." He does this effectually through the modern successful management of melancholia.

Besides the bedside treatment of disease, therefore, your calling is one of the noblest and most indispensable of the vocations of men. You sustain a most intimate relation to the people in their "hours of ease" and freedom from the presence of plainly perceptible disease. The populace is never free from the present or antecedent impress of disease upon their bodies and minds. Its active potency in preceding generations impresses itself upon the psychological character and physical power of nations as well as individuals. They rise or fall in physical prowess or moral greatness through the sanitary or unsanitary influences which promote or arrest the development or blast the life of the primordial cell, and individuals, singly or in aggregate, grow into giant grandeur or dwarf to pygmy insignificance—psychical or physical—as their physiological or pathological environment and organic antecedents permit and ordain.

This is a fact which medicine has established. This is what our profession has to teach all the people. It is the importance of medical research to the people's welfare that has led to the demand of the profession generally for higher medical education and of the American Medical Association for a National Health Department and a physician in the Cabinet, and some of you will live to see this much-needed advance accomplished. Some among you may even fill that important position. When this consummation of the people's highest welfare, "so devoutly to be wished," shall have been accomplished, then will the nation begin to realize what as yet it appreciates but faintly, that the perfection of the human species is possible only through the means supplied and ways pointed out by our profession—a fact long ago indicated by Descartes: "*S'il est possible de perfectionner l'espèce humaine, c'est dans la médecine qu'il faut en chercher les moyens.*"

The problems you will be called on to solve are those of the effects of alcohol and other drink and drug habits and vicious indulgences, and the many other devitalizing propensities and passions of our times, teratological defects, insanity, acquired and transmitted, the psychical and physical interrelation of mind and organism, the relationship of organism to mental endowments and imperfections, faulty methods of education, wrong manners of living, improper modes of travel, and some of the unsanitary social customs of the times on the generation now coming on the stage of life's action, and the entail of these neuropathic, psychical, and social vices, manners, customs, and habits upon posterity, as well as the more obvious demands of the diseased patients who will personally seek your ministrations, and of public and personal hygiene.

You are to be sanitarians in the broadest sense of the term ; educa-

tors of the people in the chief essentials of their temporal if not spiritual welfare.

The physical and psychical sanitation of the nation is in the hands of its physicians. They are the prophets whose precepts, wisely accepted and practiced by the people, will save the nation from that inevitable decadence which must attend in the future, as it has in the past, on failure to follow the true teachings of sanitary science of body and mind.

Your vocation has in it, as you see, an element of the highest patriotism.

A wise physician, skilled our wounds to heal,  
Is more than armies to the public weal.

Aim high, then, and nobly, and persevere. "Let all the ends thou aim'st at be thy God's and Truth's." Then if thou fallest, "thou shalt fall a blessed martyr." But you will not fail. And here let me recall the inspiring rejoinder of that great cardinal of France to the timid youth who ventured to suggest the possibility of a misadventure :

In that bright lexicon of youth,  
Where Fate holds forth the promise  
Of a glorious manhood,  
There's no such word as fail.

There should be no such word in your dictionary. Be brave, be true, and persevere. Train your courage by careful study of your capabilities and defects, your adaptabilities and powers. Though pluck is a plant whose seed is in the nature, it improves by cultivation. Cultivate your courage, train your powers. *Perseverentia omnia vincit, Labor omnia vincit*, are old and true working maxims for youth and age. In the conflict of life, as in physical conflict, "the battle is not to the strong alone, but to the brave, the vigilant, the active," and I am convinced, from a life of observation, that Providence assists the always courageously true and deserving, and helps to make them strong. This is my faith. Be true in every trial and falter not and you will not fail. You may often fall, but, like Antæus of old, you will rise again with renewed strength for the battle of life before you. Courage is an inspiration. Buckle on your armor and never say die. If you must fall, fall as the valiant falls, with face to the foe and defiance on your brow. Such failures are victories. They are triumphs which true courage always brings to the unvanquished soul. The bright ideals and high aspirations of this hour may not all be fully realized. Some of your fondest hopes may be cruelly crushed as you travel toward that unknown fate which awaits every mortal. The true soul is purified in fires of adversity and disciplined by its trials to deeds of greater valor. Some of you may have spent your last dollar and feel depressed and gloomy at the close of your work. To such I would say, Do not despair. Hope! Hope on! Hope ever!

With manly courage, ceaseless endeavor, and unflinching faith, push on and you shall yet see the silver lining to the clouds and the sun finally burst forth to brighten your pathway through life to a glorious future, all the more glorious for your trials. After every storm a rainbow of hope and promise skirts the sky of the brave. With faith in steady work and an exalted, honorable ambition as tributary to success, I enjoin you to apply yourself diligently, steadily, systematically, and persistently. A moderate amount of work, free from all enervating vices and interspersed with adequate recreation for recuperation and the maintenance of your physical vigor, will work a marvel of final success for each of you.

Work with your hands, work with your mind,  
Just as your nature has fitly designed ;  
Build ye a temple, hew out a stone,  
Do ye a work just to call it your own.  
Write out a thought to brighten the labor  
Of that one who reads—it may be your neighbor.  
Work as each day hastens away,  
Bearing along the grave and the gay ;  
Live out a life of excellent work.

Thus you shall weave for yourselves and mankind "garlands of work to brighten the earth."

And now, before concluding, I must remind you that your general,

as well as your special, professional education is not yet complete. It will be your duty in continuing your education to endeavor to give to your minds and bodies "all the force, all the beauty, all the perfection of which they are capable," to cultivate the good, the true, and the beautiful in yourselves and in your surroundings. This was Plato's idea of the best education. It has not been improved on since his day. It includes purity of body and mind, cleanness of heart and soul, virtue, temperance, truthfulness, and industry.

I have already advised you to aim high, to work hard, and to persevere. This is a proper ambition, but there should be even a higher purpose in life. That purpose is to so discharge one's duty as to deserve not only the approbation of mankind, but to secure the approval of God.

In your ambition to rapidly succeed, do not soil your souls with sordid avarice, "nor bend the pregnant hinges of the knee that thrift may follow fawning."

(Go forth among men . . . mailed  
In the armor of a pure intent.

Do not flatter [the world's]

Rank breath, nor bow  
To its idolatries the patient knee,  
Nor coin [your] cheeks to smiles, nor cry aloud  
In worship of an echo.

While you have a due regard for your personal interests, so practice your noble calling in the spirit of a generous love for your fellow-man that you may feel at the end of your lives that you have been true to the better elements of your nature. Conform to the dictates of your consciences in everything. Be unflinchingly true to your several convictions of duty. Listen always to that still small voice within, which, if ever faithfully obeyed, will prove your guiding star and compass to a successful and satisfactory career.

In your study of the human organism in health and disease—its growth, development, teratological and morbid entailments, and the effects of habit and environment upon it—you have seen enough to warn you, had you needed the warning of Holy Writ, that "as a man sows, that shall he also reap," in his moral as in his physical nature.

As there are "sermons in stones, books in the running brooks," and for our instruction, "good in everything," so the wise physician, from his peculiar studies, reads to himself an instructive sermon on rectitude of conduct and right moral and physical living. He knows well the physical and psychical recompenses of right and the retributions of wrong conduct, through the organism's immutable laws of well or ill being, and it will be your duty to follow the right paths and rightly lead the people. You know also of the automatisms of the mind which grow out of mental repetitions and form habits, that "as a man thinketh in his heart, so is he." That is, the thoughts he habitually cherishes make his character. This is the law of the interrelated and interdependent psychical and physical function of brain and mind; the law of mental habit.

This no preacher of the gospel of the Immaculate Immanuel could better prove to the people than the educated physician.

Finally, in the language of one of America's greatest statesmen—none other than the great Daniel Webster—let me remind you that "professional fame fades away and dies with all things earthly. Nothing of character is really permanent but virtue and personal worth; these remain. Whatever of excellence is wrought in the soul itself belongs to both worlds. Real goodness doth not attach itself merely to this life. It points to another world. Political or professional reputation can not last forever; but a conscience void of offense toward God and man is an inheritance for all eternity."

**The American Neurological Association** will hold its eighteenth annual meeting in New York, at the Academy of Medicine, on June 22d, 23d, and 24th. The preliminary programme includes the following titles:

The Pathology of Paralysis Agitans, by Dr. Charles L. Dana; Separate Provision for Epileptics, both Public and Private, by Dr. Henry R. Stedman; A Study of the Sensory and Sensory-motor Disturbances associated with Insanity, from a Biological and Physiological Stand-

point, by Dr. H. A. Tomlinson; Phthisis in its Relation to Insanity and other Neuroses, by Dr. Thomas J. Mays; The Successful Management of Inebriety, by Dr. C. H. Hughes; The Seat of Absinthe Epilepsy, by Dr. Isaac Ott; On the Extent of the Visual Area of the Cortex in Man, as deduced from the Study of Laura Bridgman's Brain, by Dr. H. H. Donaldson; The Criminal Brain, illustrated by the Brain of a Murderer, by Dr. H. H. Donaldson; Researches upon the Etiology of Idiopathic Epilepsy, by Dr. C. A. Herter; Report of Two Cases of Fracture of the Spine in which Operations were performed for the Relief of Sensory Symptoms, by Dr. Græme M. Hammond; Progressive Muscular Atrophy—Presentation of Specimens, with Remarks on the Functions of Certain Cell Groups in the Anterior Horn, by Dr. Græme M. Hammond; A Case of Brain Tumor, with Presentation of the Specimen, by Dr. Wharton Sinkler; Report of a Case of Infantile Cerebral Hemiplegia, with Autopsy (Microscopical Preparations by Dr. Warren Coleman), by Dr. E. D. Fisher; Report on One Hundred and Sixty Cases of Epilepsy, by Dr. S. G. Webber; Presentation of a Case of Huntington's Chorea, also one of Congenital Huntington's Chorea, the First on Record, by Dr. Landon Carter Gray; A Further Contribution to the Pathology of Arrested Cerebral Development, by Dr. B. Sachs; A Case of Cerebral Tumor illustrating the Difficulties of Diagnosis, by Dr. B. Sachs; Traumatic Nervous Affections, by Dr. Philip Coombs Knapp; A Note on the Use of Exalgine in Painful Nervous Affections, by Dr. W. C. Krauss; Two Cases of Severe Pressure Neuritis, by Dr. W. C. Krauss; Westphal and his Neurological Work, by Dr. W. R. Birdsall; The Association of Hysterical Trembling and Anorexia Nervosa, with the Report of a Case, by Dr. James H. Lloyd; Sleep Movements of Epilepsy, by Dr. J. W. Putnam; Diabetes in its Complementary Relations to Certain Forms of Mental Defects, by Dr. E. C. Spitzka; Imperative Movements associated with So-called Pseudo-hypertrophic Infantile Palsy, by Dr. E. C. Spitzka; A New Symptom indicating Combined Cerebellar and Spinal Inco-ordination, by Dr. E. C. Spitzka; The Basis of the Prognosis in the Traumatic Neuroses, by Dr. J. J. Putnam; Microscopic Specimens illustrating: 1. The Nerve Alterations in a Case of Beri-Beri. 2. The Nerve Alterations in a Case of Scleroderma. 3. The Alterations in Nerves excised for Neuralgia, by Dr. J. J. Putnam; Some Contributions to the Study of the Muscular Sense, by Dr. G. J. Preston; Fissural Studies, by Dr. Burt G. Wilder; Preliminary Report of the Committee on Neuronymy; Three Cases of a hitherto Unclassified Affection resembling, in its Grosser Aspects, Obesity, but associated with Special Nervous Symptoms—a Trophoneurosis possibly Related to Diseases of the Thyroid Gland, not Myxedema, by Dr. F. X. Dercum; Two Cases of Acromegaly, with Remarks on the Pathology of the Disease, by Dr. F. X. Dercum; Description of an Additional Chinese Brain, by Dr. F. X. Dercum; The Toxic Origin of Insanity, by Dr. T. H. Kellogg; Folie à deux, with Remarks on Similar Types of Insanity, by Dr. Charles K. Mills; and Three Cases of Folie communi-quée, by Dr. J. H. Lloyd.

**The American Climatological Association** will hold its ninth annual meeting at Richfield Springs, N. Y., on June 23d, 24th, and 25th, under the presidency of Dr. Willis E. Ford, of Utica, N. Y. The preliminary programme announces the following titles: An address of welcome by Dr. C. E. Ransome, of Richfield Springs; the address of the president, The Element of Change *per se* in the Climatic Treatment of Diseases; The Shurly-Gibbes Treatment of Tuberculosis, by Dr. E. Fletcher Ingals; Slow Breathing in Phthisis, by Dr. Carl Ruedi; The Treatment of Phthisis by the Pneumatic Cabinet, by Dr. C. E. Quimby; A Further Report on the Treatment of Phthisis in Colorado, by Dr. S. E. Solly; The Results of Tuberculin and its Modifications at the Adirondack Cottage Sanitarium, by Dr. E. L. Trudeau; Experience with Gnaiccol in the Treatment of Tuberculosis, by Dr. A. Jacobi; The Use of Tuberculin a Safe and Important Aid in Selected Cases, by Dr. C. Denison; The Hygiene of Bathing, by Dr. F. H. Bosworth; The Classification of Mineral Waters, by Dr. A. N. Bell; Heart Failure, by Dr. A. L. Loomis; Altitude in Affections of the Heart, by Dr. Frederick I. Knight; Cardiac Disease Consequent on Epidemic Influenza, by Dr. R. G. Curtin; The Effect of Change of Posture on Heart Murmurs, by Dr. V. Y. Bowditch; a discussion on The Influence of Bacteriological Investigation on Preventive Medicine; Underground Water Currents,

Causes and Results of Deflection, by Dr. Leroy J. Brooks; and The Causes of Death in Lobar Pneumonia, by Dr. G. R. Butler.

The American Laryngological Association will hold its fourteenth annual congress in Boston, in the hall of the Natural History Society, on June 20th, 21st, and 22d, under the presidency of Dr. S. W. Langmaid, of Boston. Besides the president's address, the programme gives the following titles:

The Present Status of the Treatment of Hay Fever, by Dr. C. E. Sajo; The Influence of Certain Diathetic Conditions upon the Prognosis in Operations upon the Throat, by Dr. D. Bryson Delavan; Some Pathological Conditions of the Upper Air Passages accompanying *La Grippe* Attacks, by Dr. S. Hartwell Chapman; Pharyngo-mycosis, by Dr. F. I. Knight; A Case of Carcinoma at the Base of the Tongue, by Dr. Jonathan Wright; A Case of Cancer of the Tonsil treated by Lactic Acid, by Dr. E. Fletcher Ingals; Report of Some Cases of Membranous Sore Throat, by Dr. Beverley Robinson; Intubation for Chronic Subeardal Stenosis of the Larynx in a Boy Twelve Years of Age, by Dr. C. H. Knight; Rare Forms of Laryngeal Growth, by Dr. Alexander W. MacCoy; A Case of Tumor of the Larynx, by Dr. H. L. Swain; Two Cases of Laryngectomy for Malignant Disease, by Dr. J. Solis-Cohen; The Value of Sprays in the Treatment of Catarrhal Affections of the Upper Air Passages, by Dr. Clarence C. Rice; Nasal Hydrorrhœa, by Dr. C. E. Bean; An Eligible Method of repairing a Broken Nose, by Dr. W. H. Daly; The Correction of Deformity resulting from Abscess of the Nasal Sæptum, by Dr. John O. Roe; The After-results of Nasal Cauterization, by Dr. T. A. DeBlois; Diseases Incidental to the Frontal Sinus, by Dr. D. N. Rankin; and A Case of Suppurating Ethmoiditis, by Dr. J. H. Bryan.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. Walter Wyman, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for June 10th:

CITIES.	Week ending—	Population, U. S. Census of 1890.	Total deaths from all causes.	DEATHS FROM—											
				Phthisis pulmonalis.	Yellow fever.	Small-pox.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Menses.	Whooping-cough.

Chairmen of Committees on Anatomical and Biological Nomenclature; Correction.—In a circular entitled American Reports upon Anatomical Nomenclature issued last winter by Professor Wilder, as secretary of the committee of the Association of American Anatomists, in the third paragraph of the third page, the chairman of the committee of the Anatomische Gesellschaft should be Professor A. von Kölliker, and the chairman of the American division (appointed in 1891 by the American Association for the Advancement of Science) of the Interna-

tional Committee on Biological Nomenclature should be Professor G. L. Goodale. Professor Wilder desires to express his regret for the errors, due in the one case to his own misapprehension and in the other to a clerical mistake.

The late Dr. William R. Birdsall.—At a meeting of the medical board of the Manhattan Eye and Ear Hospital, held on June 10th, the following preamble and resolution were adopted:

Whereas, It has pleased Almighty God to remove from our number Dr. William R. Birdsall, one of the physicians to this hospital;

Resolved, That in bowing to his will we desire to express our esteem and love for Dr. Birdsall as our colleague and friend, and our sense of the great loss sustained by the hospital in the removal of one of our most faithful and efficient workers, who has made valuable contributions to the science of medicine; that the sincere sympathy of this board be extended to his family in their deep affliction; that the board in a body attend his funeral; and that these resolutions be spread on the minutes of the board and be published in the *Medical Record* and the *New York Medical Journal*.

[Signed.] D. B. ST. JOHN ROOSA, M. D., CHARLES H. KNIGHT, M. D.,  
President. Secretary.

To Contributors and Correspondents.—The attention of all who purpose favoring us with communications is respectfully called to the following:

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

POTT'S FRACTURE AT THE ANKLE.\*

By LEWIS A. STIMSON, M. D.,

SURGEON TO THE NEW YORK AND CHAMBERS STREET HOSPITALS.

At the time when the courteous invitation of your secretary to read before you a paper "on some practical point connected with fractures or dislocations" reached me I had under treatment three cases showing unusual varieties of a common fracture. It is one in which I have long felt an especial interest as a hospital surgeon and a teacher, because of what I believe to be the frequency with which cardinal points in the treatment are overlooked and because of the occasional great disability that results. The idea which at once suggested itself—that the injury in question was an appropriate subject for the desired paper—was confirmed on reflection, and I therefore ask your attention to a consideration of some points connected with the diagnosis and treatment of Pott's fracture at the ankle.

Certain variations in the current use of the name and in the classification of injuries at the ankle make it desirable to define at the outset the injury we have in mind. By Pott's fracture at the ankle I mean that common injury produced usually by a forcible twist of the foot outward, and consisting (typically) of (1) a fracture of the fibula from one to three inches above the tip of the malleolus, (2) a fracture of the internal malleolus or a rupture of the internal lateral ligament, and (3) a diastasis of the lower tibio-fibular articulation with rupture of its ligaments, or possibly with avulsion of the adjoining portion of the tibia.

Of these lesions, the fracture of the fibula is, clinically, the most striking and the most easily recognized, and this fact has a constant and well-marked tendency to fix the attention upon this one of the three lesions to the exclusion, or at least to the subordination, of the others—a tendency that is full of danger for the patient for reasons that are apparent on a closer examination. The fracture appears usually to be oblique, often very markedly so (in a specimen of my own the line of fracture is more than two inches long), but the maximum of crepitus and abnormal mobility appears on manipulation to be well above the malleolus, a feature which is ordinarily sufficient at once to distinguish this form of fracture from another of much less importance which is apparently produced by *inversion* of the foot, and in which the line of fracture is situated at or near the base of the malleolus. A few cases have been recorded in which the fracture was in the middle third of the fibula or even still higher; and in some of my cases the fibula was unbroken, a point to which I shall return in a moment.

The lesion that stands second in clinical prominence is the fracture of the internal malleolus or the equivalent rupture of the internal lateral ligament. In this the varia-

tions in the position and extent of the injury are more striking than in the preceding one. The common form is rupture of the ligament, the less common one is fracture; and the fracture presents two typical forms. One of them is the equivalent of rupture of the anterior portion of the ligament, and has the same mode of production; in it only a small portion of the malleolus—an antero-inferior fragment—is broken off, the line of fracture being oblique upward and forward. In the other the whole malleolus is broken square off at its base, and the mode of production is quite different, as will be subsequently explained; in my experience it has always coincided with the extreme outward displacements of the foot.

The third lesion is the rupture of the ligaments of the lower tibio-fibular articulation. In a few recorded cases, instead of rupture of the anterior ligament, avulsion of the portion of the tibia to which it is attached has taken place; in only very few of the specimens which I have had an opportunity to examine, either post mortem or in the course of an operation or of an experiment upon the cadaver, have I found this fracture, and then it has been only an avulsion of a superficial scale of bone; I believe that even such superficial fracture is rare.

The effect of this rupture or avulsion of the ligament is to loosen the mortise within which the astragalus is held and thus to permit the displacement of this bone (and, of course, of the foot) outward. The displacement thus made possible is at once effected by the continued action of the vulnerant force; and if the weight of the individual is then brought upon the foot, the lack of coincidence between the point of support at the heel and the long axis of the leg leads instantly to further displacement in the same direction, and possibly to important additional injuries. Another result of this loosening of the mortise—one which is of much practical importance but which has received only scanty attention in systematic treatises—is the backward displacement of the astragalus along the lower surface of the tibia. This may be slight—an eighth, a quarter of an inch—or so great that the body of the astragalus lies wholly behind the tibia. It is effected in part by the contraction of the sural triceps and in part by gravity when the limb is supported in the usual horizontal position. I have never seen the extreme form in cases less than twenty-four hours old, and I associate it, not with corresponding severity in the causative violence, but with persistent, unopposed action of the sural muscles—in other words, with absence of treatment or with defective treatment.

If these two displacements, the outward and the backward, remain uncorrected, the resultant disability is great. The former removes the point of support so far to the outer side that an excessive strain is brought, in walking, upon the ligaments on the inner side of the ankle, and the patient is soon compelled to stop. The backward displacement, if slight, limits the range of flexion of the joint; if great, it abolishes it completely.

Except in the more marked cases, and unless specifically sought for, this diastasis of the tibio-fibular joint and the symptoms to which it gives rise can be easily overlooked,

\* Read by invitation before the Massachusetts State Medical Society, June 7, 1892.

and yet it is the essential lesion of the injury—one which vastly outweighs the fracture of the fibula in importance (as we have seen, the latter may even be absent), and one without which the lesions on the inner side of the ankle would probably be impossible. Without correction of this displacement and repair of these torn ligaments, a satisfactory recovery from the injury can not be had. This, then, is the feature which characterizes the injury and dominates the treatment. It is by the recognition of its presence that the diagnosis is made, and by the completeness of its repair that the efficiency of the treatment is measured.

This rupture of the tibio-fibular ligaments and the outward displacement of the foot were recognized by Dupuytren and have formed part of most systematic descriptions since his time, but the current notion of the change in the relations of the parts has always been, and apparently still is, that which is indicated in Percival Pott's original illustration, and it seems not unlikely that this illustration is responsible for it, for it has often been reproduced and is still doing duty. This notion is that the astragalus and the lower fragment of the fibula have been rotated ten or twenty degrees about an antero-posterior axis passing through the tibio-fibular joint, so that the upper end of the lower fragment is pressed inward against the tibia, the apex of the malleolus is directed obliquely outward, and the upper surface of the body of the astragalus is separated from the articular surface of the tibia by an angular space which is widest at the inner side. This conception of the change is erroneous: there is no angular change in the relations of the astragalus and tibia, but the former has simply slipped sideways along the latter; the upper end of the lower fragment of the fibula has not been displaced inward (indeed, a glance at the skeleton will show that there is no room for such a displacement), but the lower part of that fragment has been pushed outward by the displaced astragalus.

The *mode of production* is, clinically, sometimes quite clear, as when the foot is fixed and the body is thrown toward the same side, or, the foot being fixed, the lower part of the leg is pressed forcibly inward; in either case fibular flexion (eversion of the sole) is made at the ankle. This mode of production is relatively infrequent; to it belong the square fracture of the malleolus at its base and the extreme displacements of the foot outward that are sometimes noted. In some of them I have also found the lower fragment of the fibula smaller and more movable than usual. It can be copied upon the cadaver with great precision by fixing the os calcis in a vise and pressing the upper part of the leg outward.

Clinical proof of what I believe to be the other and much the more common mode of production is exceedingly difficult to obtain, notwithstanding the frequency of the fracture. Patients can seldom say more than that they slipped and twisted the foot; most of the few who can specify the direction of the twist say that it was outward; one of my patients insisted that his foot turned inward, but he added that when he rose after the fall and tried to walk he felt and heard something break at the ankle, so that the case can not serve as evidence that inward rotation can produce the lesions. Occasionally the mechanism seems clear, as in two

cases under my care this spring: in one of them, while the patient was kneeling on one knee, the foot resting on the hyperextended toes, he was pressed back by another man so that his buttocks rested on and forced the ankle inward, causing abduction of the front of the foot. In the other the patient was lying on his side on the floor, with his foot projecting beyond the edge of an elevator shaft; the descending car struck the inner side of his foot; the man hastily arose and withdrew his foot, so that it bore the pressure only for a moment; he received the second and third type lesions, as above enumerated—rupture of the internal lateral and tibio-fibular ligaments—but escaped without the first, fracture of the fibula.

Experimental proof that such abduction of the anterior portion of the foot as appears to have taken place in these two cases is competent to produce the fracture, is easily obtained on the cadaver by fixing the leg and forcing the toes outward while the ankle is held at a right angle. If the limb is previously prepared by dissection so that the sequence of events can be followed by the eye in detail, it will be seen that the first to yield is the anterior tibio-fibular ligament, then the anterior fibers of the internal lateral ligament, and, almost coincidentally, the fibula breaks by the twisting of its lower end, the line of fracture being very oblique in such a way as to make the upper fragment terminate in a posterior point near the level of the ankle joint. If the tibio-fibular ligament is first divided by the knife it is interesting to see how promptly abduction of the front of the foot makes the tibio-fibular joint gape. That the same sequence occurs clinically is shown by the cases in which the fibula remains unbroken, the action of the force having been arrested before the injury was complete. In one unique case I saw an interesting variation: dislocation of the external malleolus backward from the tibia while its relations to the astragalus and os calcis were preserved; it was caused by an outward twist of the foot while wrestling, and could be easily reduced and reproduced by pressing the front of the foot inward and outward respectively. Some hesitation must be felt in generalizing upon these facts and claiming that abduction of the front of the foot is the one cause of the common form of the fracture, for it is a forced movement to which we do not seem to be so much exposed in the common missteps and slippings as the great frequency of the fracture\* would suggest. Possibly, careful questioning of the more intelligent patients will yet remove the doubt, or perhaps some fortunate one of us may repeat the experience of Pott and, in himself suffering the injury, gain the knowledge that will associate his name also with that of the fracture.

The *diagnosis* can be made with great ease and certainty by the recognition of the points of fracture and of abnormal lateral mobility in the joint and by the deformity, which, even when slight, is so characteristic that the diagnosis can often be made with considerable assurance by the eye alone. I have spoken of the diastasis of the lower

\* This frequency is shown by the following statistics: During the six months ending June 1, 1892, the following fractures of the head, trunk, and lower extremity were brought into my service at the Chambers Street Hospital by ambulance; fractures of the upper ex-

tibio-fibular joint as the essential lesion, and it is upon this, therefore, that I think the positive diagnosis should rest. It is indicated by one subjective symptom—pain on pressure with the tip of the finger at the junction of the two bones in front close above the articular edge of the tibia; and demonstrated by one objective sign—abnormal lateral mobility—which can be shown by grasping the foot with one hand so that the posterior portion of the sole rests in the palm, with the thumb close below the external malleolus and the index finger below the internal malleolus, and moving it bodily inward and outward, while the other hand grasps the leg well above the ankle and steadies it (Figs. 1 and 2). Sometimes the click of the astragalus against the internal malleolus in this manipulation is as distinct as that of the patella against the femoral condyles when it has been raised by an effusion. The advantage of this manipulation is not found solely in the certainty it gives to the diagnosis; it also calls attention in no doubtful terms to the essential points in treatment, and it impresses him who makes it, more than any verbal injunctions could do, with the necessity of actively opposing the tendency to displacement—for he sees the foot slip outward the instant he removes the pressure of his thumb; he sees the necessity of *holding* it in place, not simply of *putting* it in place.

This immediate reproduction of the displacement appears to be due in part to the contraction of the peroneal muscles, and it may be well to add that, when these and the other muscles of the leg are kept contracted by pain or the fear of pain, this demonstration of abnormal mobility is thereby made distinctly more difficult. The difference appears at once on the administration of an anæsthetic.

I would also call attention to the usual absence at the bedside of what is a common symptom in the books—eversion of the sole. (See Fig. 1.) In my experience this is rarely present; only when the outward displacement is exceptionally great or the peroneal muscles tense.

tremity, being relatively infrequent in ambulation cases, are not here included.

In all but the slightest cases there is also a second constant displacement, which can be as readily demonstrated as the former, and which recurs as readily if measures to prevent the recurrence are not taken; it is a displacement of the foot backward, ordinarily for not more than a quarter of an inch. It is demonstrated by grasping the foot with both hands so that the fingers rest on the back of the heel and the thumbs on the front of the lower end of the tibia, and then, the sole being vertical, lifting the foot with the fingers while the leg is held back by the thumbs, and then allowing it to drop back again. This displacement is effected partly by gravity, partly by the contraction of the muscles of the calf. It is more easily recognized by the eye when the foot is in plantar flexion, for then a distinct notch can be seen in the dorsal outline immediately below the articular edge of the tibia (Fig. 3); but—the importance of the point justifies the reiteration—unless the surgeon's attention is specifically directed to the detection of this displacement and also of the outward one, they will both, as a rule and except in the most marked cases, pass unrecognized. This statement is justified by the frequency with which this failure to recognize has been observed; and a belief in this frequency and in that of defective treatment due to it is the main reason for bringing the matter before this society. Some of the photographs already shown—those of the old unreduced cases (Fig. 5)—prove how great a displacement can pass unrecognized; and in three cases that had been treated in large hospitals and subsequently came under my care for the relief of the disability, the body of the astragalus lay wholly behind the tibia. And yet in one of these cases the hospital record states that the patient was “discharged cured.” Of course, the failure to recognize such marked deformity at the end of treatment, after all swelling had subsided, must have been due to inattention; but the inattention is proof of a failure to appreciate the possibilities of the injury.\* It is, nevertheless, a fact that such extreme backward displacement can pass unrecognized in recent cases even by experienced observers who are aware of the possibility and have specifically sought for the displacement. They make the usual manipulation, which should effect its reduction if it is present, and, as the foot does not come forward, they infer that the displacement does not exist. And it must not simply be conceded that the displacement can be overlooked; we must appreciate that it may be difficult not to overlook it. The muscles are held tense, and the foot does not yield to the surgeon's effort to move it forward; he doubts his observation; he again scrutinizes the profile of the foot. An abiding faith in the significance of certain apparently slight deviations from the normal is necessary to save the surgeon from a grave error and the patient from a serious disability. Anæsthesia,

\* It is interesting to note, in some of these neglected cases in which the deformity is very great, that, while there appears to be a great outward displacement (Fig. 4), it is actually, almost solely, a backward displacement, and that the prominence of the internal malleolus is due to the fact that the displacement is along a line that makes an angle with the axis of the foot, so that the anterior portions of the foot, as they are successively brought back to the line of the internal malleolus, lie further and further to the outer side.

pushed to complete muscular relaxation, clarifies the situation; the foot comes at once forward and inward for a distance that is always startling, and which vividly suggests that charity in judgment is not only a grace which we may amiably extend to others, but is also one of which we may at any moment stand urgently in need ourselves.

To summarize it: Pott's fracture may be diagnosed by the recognition of three points of localized tenderness on pressure—one over the front of the lower tibio-fibular articulation, one at the seat of the fracture of the fibula two or three inches above the apex of the malleolus, the third at or just below and in front of the internal malleolus. These having been found, examination should be made by the methods indicated to detect outward and backward displacements and lateral mobility.

The indications for *treatment* (reduction and retention) have long been well understood; it is only necessary to emphasize the importance of meeting them thoroughly and permanently, and to point out the probability of being misled if one trusts to the eye alone to estimate the completeness of the reduction of the displacement. In the cases of extreme backward displacement, as has been already said, anaesthesia may be necessary to annul muscular opposition to reduction, and the same condition of the muscles occasionally makes its aid necessary in the slighter cases, either to effect reduction or to maintain it until the dressing shall have been applied. The indication, in the common run of cases, is simply to bring the external malleolus back to its place alongside the tibia, to hold it there until the torn ligaments and the broken bones have reunited, and thus to re-establish the mortise with the astragalus within it. This is accomplished by the aid of the ligaments that unite the malleolus to the astragalus and calcaneum; if the foot is brought back into place, the malleolus must go with it. But it must be remembered that in this re-establishment of the normal position of the foot it is upon its posterior portion alone that our efforts and our attention must be fixed; it is the astragalus that is to be brought into place, and the attitude of the front of the foot is not much more of an indication of the position of the astragalus than the attitude of the forearm is of the position of the head of the humerus. The posterior portion of the foot, the heel, must be pressed forward and inward, and must be held in place by pressure made against the outer side of the calcaneum and cuboid; the first effect of this pressure is to move the calcaneum and the rest of the tarsus inward along the lower surface and front of the astragalus—or, in other words, to invert the sole and adduct the front of the foot—and only after this movement has reached its limit and the ligaments have become tense does the pressure take the desired effect upon the astragalus and malleolus. Consequently, the rule should be to press the foot inward as far as it will go, adding inversion of the sole and adduction of the front of the foot, as shown in these photographs. There is no danger that the movement will be carried too far; the astragalus can not move a hair's breadth inward beyond its proper position; that is prevented by the internal malleolus or by the arrest of the fibula by the tibia, and, however distorted the position may seem, the distortion

is wholly in front of and below the ankle, and within the limits of a normal range of motion. Let me repeat: This inversion is not a superfluous addition to the treatment; it is the most convenient and trustworthy means of preventing the recurrence of outward displacement.

It is also necessary that the heel should be supported to prevent backward displacement.

These indications are satisfactorily met by molded splints of plaster of Paris, applied as shown in the photographs (Figs. 6 and 7). I prefer them to complete incasement because they permit inspection of the inner side of the ankle and immediate detection of recurrence of the displacement, and I prefer them to single or double lateral wooden splints because they are less liable to shift or to permit recurrence. They can be made of any loose-meshed material and plaster cream, or, very conveniently, of the common four-inch plaster roller. If made of the latter or of any other gauze, they should have twelve or fifteen thicknesses. The posterior splint should extend from the toes, along the sole, around the heel, and up the calf nearly to the knee; the lateral one should begin just in front of the external malleolus, pass over the dorsum of the foot to the inner side, under the sole, and upward along the outer side of the leg to the same height. They are molded and bound to the leg while wet with an ordinary roller bandage, which should be removed after the plaster has set, its place being taken by a few turns of a bandage just above the ankle and at the upper end of the splint. It is advantageous to have the splints wide enough to overlap along the side of the leg, and thus give greater security against shifting.

Such a splint may be put on immediately after the accident without fear of strangulation, if the supporting circular bandages are watched and loosened if there should be need. If put on while the limb is swollen, the subsequent shrinking can be met by tightening the circular bands; but it is advisable to apply a new one after a few days.

In the treatment of old fractures with much deformity the point of capital importance is, of course, the recognition of the direction and extent of the displacement, the appreciation of the fact that the astragalus and external malleolus are dislocated backward, and that the very noticeable projection of the internal malleolus is to be relieved by bringing the foot forward, not inward. I have always used two lateral, or antero-lateral, incisions. One begins at the front of the fibula, three inches above the ankle joint, is carried down along the bone, passing in front of the displaced malleolus, and then curved forward on the side of the foot; the seat of fracture is exposed, and the lower fragment again separated from the upper one. The second incision begins on the inner side of the tibia at about the same level as the first, passes down to the front of the malleolus, and thence forward to or beyond the tubercle of the scaphoid. Through it the internal malleolus can be detached with a chisel, and the end of the tibia protruded so that it is easy to liberate and mobilize the astragalus and to cut away any new growth of bone that may have formed on the back of the tibia. The foot is then easily restored to its place, the incisions closed with out drainage, and a bulky dressing applied and covered

with plaster of Paris. I change the dressing at the end of a week or ten days, and then apply a light plaster-of-Paris dressing. The patient is allowed to begin to bear his weight upon the foot in the fourth week. The photographs (Figs. 8 and 9) show the results as regards the restoration of form. The gain in function has also been very satisfactory.

Finally, if a few moments more may be allowed me, I should like to call attention to two complications of this injury which I have encountered in four cases and which have not heretofore been noticed. In two of these cases the internal malleolus was squarely broken off at its base and had undergone a rotation of 90° on its antero-posterior axis, so that its fractured surface lay parallel to and just beneath the skin. When the first patient came under my observation (in 1888), a few hours after the accident, the malleolus formed a prominent, freely movable mass; that it was the malleolus could not be doubted, but I was quite at a loss to explain its prominence and its mobility, or rather its unstable equilibrium, for it rolled about freely, but did not shift its position. I exposed it by an incision, discovered the condition, and easily turned the fragment back into place. When the second patient presented himself (1892), the diagnosis was easily made with the aid of what had been learned in the preceding case; it was treated in the same manner. Both patients recovered from the injury and the operation with full restoration of function, and both were shown to the New York Surgical Society. It seems probable that if such a displacement were allowed to remain uncorrected the solidity of the joint would be seriously impaired.

In the third and fourth cases the complication was also marked by exceptional prominence and mobility of the fractured malleolus, and the cause was found, on exposure of the parts by incision, to be the interposition between the fragments of a long strip of periosteum that had been torn from the inner surface of the tibia in one, and of a smaller strip of periosteum and a portion of the anterior annular ligament in the other. In both cases recovery followed without incident and with full restoration of function.

## TUBERCULAR GLANDS OF THE NECK.

ENLARGED glands of the neck in children may be grouped in two classes: (1) the tubercular; (2) the simply hypertrophied gland. The vast majority, in my experience, belong to the first class, while those belonging to the second have been but occasionally met with. They are due to some irritation about the head; they never suppurate, and subside as soon as their exciting cause has been removed. They are most frequently secondary to pediculi or eczema capitis.

On the other hand, a tubercular gland or glands have been found whose origin seemed to be due to the same

cause, so that the existence of disease of the scalp in connection with enlarged glands can not be considered as a proof that the disease of the gland is not of a tubercular nature.

The tendency of a tubercular gland is toward caseation, calcareous degeneration, or abscess; they seldom undergo resolution. The deposit, if small, may become encapsulated, and, in rare cases, give no further trouble, but, as a rule, an abscess slowly forms, opens, and continues to discharge until all diseased tissue has been eliminated, leaving unsightly scars and blemishes, so often seen.

From the experience derived from these cases, the inference has been drawn that one or many tubercular glands of the neck are not a symptom of general tuberculosis, except in rare instances; thus, in sixty-one cases, in only three children have these glands been known to be accompanied by tubercle in other parts of the body, and in these the enlargement of the glands of the neck followed, not preceded, tubercular deposits elsewhere. Most of the cases operated upon have been seen or heard from at various times since the patients left the hospital, and, with but two exceptions, not a single one is known to have died from tuberculosis. From the above it would seem that tubercular adenitis is a local, not a general, affection, and that the danger from general infection is not great. This deduction, it must be understood, is personal from a hospital experience.

Clinically, tubercular glands of the neck have been met with under two conditions: (1) The large, isolated gland or glands; and (2) a number of small or moderately enlarged glands blended together by inflammatory products.

Of the first class, the number of glands involved has varied; in some cases only one, in others two or more glands have been diseased—if there has been more than one on a side. They are separated by more or less normal tissue, unless there has been a periglandular abscess with its secondary inflammatory changes; but they have never been found matted together, as in the second class. The contents of these glands have always been of a tubercular nature, the amount found depending upon the size the gland has attained. The larger the tumor, the more has the glandular been replaced by tubercular tissue, so that in many examples the contents of the capsule were formed entirely of caseous and semi-liquid material. These glands vary much in size; some are but little enlarged, while others attain considerable size. The largest removed measured three inches in their largest diameter. In older glands the more fluid portions of these contents may be absorbed and calcareous material found.

The course pursued by these glands varies. In a few cases, after attaining a large size, there has been no further increase, but a gradual diminution in size, their more liquid contents being absorbed and replaced by calcareous matter, the capsule shriveling up, and no further trouble is ever experienced. This course is not always followed, however, even in glands whose contents have undergone absorption. Often, in opening an abscess of the neck, nothing is found to account for its presence but calcareous material which has escaped from an old atrophied gland and has set up a tubercular abscess.

In those glands whose contents do not follow the course

mentioned above, after a time the capsule gives way at some point and allows the escape of infected material into the surrounding tissue and a tubercular abscess is slowly formed, which often attain considerable size, perforating the skin; finally a sinus remains with undermined and unhealthy skin; this sinus may discharge for years, leaving behind it deformities and unsightly cicatrices.

The second class consists of small or moderately enlarged glands, often consisting of a chain of glands blended together in a mass by inflammatory products. These masses form large swellings in the neck. On examination, these tumefactions are found to consist of a chain of glands of different sizes and in various degrees of tubercular degeneration. They have not been met with as frequently as the isolated gland. They are often deeply seated behind the deep fascia of the neck, and they are difficult to deal with.

It may be laid down as an almost universal rule that a chronic abscess in the neck of a child, if not connected with bone disease, has its origin in a tubercular gland. Sometimes these abscesses are rapid in their formation, are accompanied by marked constitutional symptoms, the tissues of the neck are brawny, and much pain is complained of. This, however, is not the rule. Tubercular abscesses generally are slow in their formation and unaccompanied by any marked symptom but swelling.

These abscesses may form behind the deep fascia of the neck as a firm, well-defined swelling, and one in which no fluctuation can be detected. One side of the neck looks fuller than the other. The true nature of this may not be known until the deep fascia has been perforated and the abscess cavity entered. In other cases a large superficial abscess may be opened and no diseased gland found. If, however, careful search be made with a director on the floor of such an abscess, a small opening will be found in the fascia leading to a tubercular gland. The history of such a condition is as follows: An abscess has formed connected with a tubercular gland behind the deep fascia. After attaining considerable size a small opening is formed in the fascia, and the contents of the post-facial abscess slowly empties itself through this channel into the subcutaneous tissue of the neck; finally, all the fluid contents of the deep collection of pus finds its way into the superficial abscess, the tubercular gland and abscess being connected by a sinus.

The importance of searching for such an opening is evident, for no cure can be accomplished until the contents of the deep-seated, diseased gland have been removed.

*Treatment.*—The medical management of tubercular glands is far from satisfactory. The general routine treatment with tincture of iodine is worse than useless. The indications are for *soothing*, not *stimulating*, applications. It is safe to say that painting with tincture of iodine tends to increase the tumefaction rather than diminish it. Poulitices should have no place in the management of these cases; they make the skin sodden, and increase rather than retard suppuration. If an abscess has opened, they are worse than useless. Moist heat encourages bacterial growth, lowers the vitality of the skin, and favors undermining.

Rest to the neck, tonic treatment, change of air, if possible, the removal of any nose, throat, or ear trouble, and maintaining the scalp in a healthy condition, are the means best calculated to be rewarded by success in cases in which much tumefaction has not taken place. Tubercular deposits in the gland differ in no respect from that in other portions of the body. They follow precisely the same course, and should be viewed from the same standpoint.

It is perfectly useless to attempt to treat a tubercular gland that has attained any size by medication with the expectation of its cure. It will always remain a diseased gland, and, in the vast majority of cases, will eventually suppurate.

The best treatment for a tubercular gland is its enucleation. If removed before its contents have infected the surrounding tissue, it prevents the formation of an abscess; and if suppuration has taken place, an operation shortens its amount and duration by months, or even years, obviates unsightly scars, and prevents the infection of other glands. For these reasons the surgical management of this affection is to be advocated.

As to the question when an operation should be done, it is always better to anticipate the formation of a periglandular abscess, and, in order to do this, all chronically enlarged glands of a tubercular nature, if of any size, should be removed, as by so doing time will be saved, and the scar resulting from the incision will only be linear and in time will be scarcely noticeable.

In regard to abscesses about the neck, the rule should be that they be opened, their cavity thoroughly curetted, together with any diseased glands, as soon as possible, and, above all, in no case should a poultice be applied.

The method of operating that in my hands has been proved satisfactory is as follows:

*In Cases Unaccompanied by an Abscess.*—After disinfecting the skin, an incision is made over the enlarged gland, if there is only one, or over the most prominent, if more than one is involved, down to its capsule, the incision being, as a rule, not more than an inch or an inch and a half long. Into this cut the gland is made to protrude as much as possible by grasping it behind. If it is non-adherent, it can be separated from its loose connection by means of a director, or, what is better, an artery needle used very much as strabismus hooks are used in enucleating an eye, working around the gland with the hook and a pair of blunt, curved scissors until the hilus is reached. If it has been thoroughly freed from all its other attachments, the gland can now be forced entirely out of the wound, its only attachment being at the point where the vessels enter. A catgut ligature is then applied around these and the gland cut away. Unless some vessel has been divided in the soft parts, there will be little, if any, hæmorrhage. If there are other diseased glands near the one removed, they can usually be reached through the incision already made. If, however, this can not be done, the incision can be enlarged or a new one made. It is often astonishing how much can be done through one opening.

If a gland is adherent, its removal is tedious and not safe; for such, the better plan is to open the capsule and

thoroughly remove its contents with a Volkmann's spoon, leaving the capsule behind. If the capsule has been opened during the operation, or its contents have perforated it before the date of operation, infecting the surrounding tissue, the same plan can be adopted, only the spoon must be used freely over the whole extent of the abscess cavity; all diseased tissue *must be removed*.

In those cases where a number of small or moderately enlarged glands are matted together, and when from their situation there is danger of injury to important vessels or nerves, it has always seemed better to remove such as can be safely and easily done, thoroughly curetting the cavity of any abscess that may exist, dividing the capsule and removing the contents of as many diseased glands as possible without making large incisions and tedious dissections. In some of these cases the glands are so situated that their thorough removal is easily accomplished without any danger to other structures, while in others a formidable operation will be required to remove them. A good result has followed in all cases where this plan has been adopted, although a second and sometimes a third operation of curetting has been called for.

In old cases where abscesses have been allowed to pursue their natural course and sinuses exist, there is often found much tubercular tissue within their cavity. In such cases a thorough curetting will effectually remove all infected tissue and a rapid closing of the cavity will result. Where the diseased gland is deeply seated and where there exists a superficial abscess connected with the gland by a small sinus through the fascia, the diseased gland can be easily removed by passing a small or moderately sized Volkmann's spoon through the sinus and curetting the gland. Unless this is done, the opening in the skin will not close until all infected tissue has been eliminated. After clearing out these cavities and glands as thoroughly as possible with a Volkmann's spoon, a moderate-sized sponge, dampened with mercury solution, is caught in a locked forceps and forced into the cavity and then turned around several times. This will remove and bring away any diseased tissue that may have been left by the spoon.

If the skin is thin, undermined, and unhealthy in appearance about a sinus, it is freely removed.

After the clearing process has been finished, the wound is well washed with mercuric solution (1 to 1,000), then dried with a sponge and iodoform dusted in, and the parts brought together as thoroughly as possible with deep and superficial suture so as to leave as few "dead spaces" as possible. It will sometimes be found, however, that the parts can not be sutured so as to close entirely the deeper portions of the wound. In such cases the wound has been stuffed with iodoform gauze.

In regard to the skin wound, one of two methods has been adopted—either to close it with a subcutaneous catgut suture, or, if the abscess has been subcutaneous or the gland large and its removal has left a considerable subcutaneous cavity, the needle, armed with the suture, is passed from without inward some distance from the edge of the incision through the whole thickness of the skin into the cavity; then, on the opposite side of the cavi-

ty, from within outward to a corresponding point upon the other side, then back again, and repeated until a sufficient number of continuous sutures have been passed, the last ending on the side first perforated. The two ends are then tied tightly together, bringing the inner walls of the cavity in apposition and causing a prominent ridge on the neck. The advantage of this is that it helps to obliterate the cavity, and, when the catgut is absorbed, the skin assumes its normal position. It has been found to be no small gain.

In regard to drainage, for some time rubber drainage-tubes were used, but of late they have been abandoned. Their points of entrance were always slow in closing, and seemed to increase the amount of cicatricial tissue. In their place horse-hair has been substituted, a bunch being held in place by the skin suture, its ends protruding from either extremity of the wound; it affords ample drainage. It is easily removed, and does not leave the cavity always seen when rubber tubing has been used.

It is not to be supposed that in all cases of operation upon tubercular glands of the neck the wound closes up at once. In many, owing either to imperfect eradication of the diseased tissue, error in after-treatment, or new points of disease showing themselves, suppuration follows. Sometimes after the wound has closed it will break down again and discharge, or a sinus will persist, the edges of the wound assuming an unhealthy appearance. In such cases the wound must be reopened. It will then be found that the old cavity has refilled with tubercular matter and pus, a neglected gland having reinfected the parts; or, if no gland be found, it is due to diseased tissue that had not been removed; but, whatever its cause, unless the cavity is again cleaned out, no permanent benefit will be derived from the operation, and a sinus may continue to discharge for months.

In other cases, although the old point of disease may never give any trouble, new glands may become enlarged and call for another operation. Thus in one child I have operated ten times for the last four years. She has had no return, and is a perfectly healthy-looking girl.

The ultimate result after the surgical treatment of tubercular glands is that, if the gland is removed before a periglandular abscess has formed, the resulting scar will be linear and scarcely visible. If, however, an abscess has formed and the skin is much undermined and unhealthy, the amount of cicatricial tissue will be in direct proportion to the amount of diseased skin. In other cases, even in the presence of an abscess, a linear scar may be formed.

The following are the statistics of all cases operated upon:

Number of cases, 58. Of these, 25 occurred in males and 33 in females.

Abscesses are mentioned in 20 cases; none existed in 28; not mentioned in 23. Age: Eleven patients were two years old; 11 were three years old; 3 were four years old; 5 were five years old; 2 were six years old; 6 were seven years old; 6 were eight years old; 1 was nine years old; 6 were ten years old; 4 were eleven years old; 1 was twelve years old; 1 was thirteen years old; 1 was fourteen years old.

The shortest time that the patient was under treatment was nine days; the longest, three years.

The duration of treatment was as follows: Fourteen patients were in the hospital less than three weeks; twenty were discharged at the end of a month, twelve at the end of two months, five at the end of three months, two at the end of four months, two at the end of five months, one at the end of six months, and one at the end of seven months; and two were under treatment for three years.

In the two patients who were under treatment for three years, in one ten operations and in the other eight were performed; some of them were for simple curetting, while on other occasions recently infected glands were removed.

In two cases only has there been any troublesome hæmorrhage, and this was in connection with masses of glands; during an attempt to enucleate them a vein of considerable size was torn, and for a short time there was quite a sharp hæmorrhage until the vessel was secured by a ligature. Care must be taken not to drag much on these matted-together glands.

After an operation the neck is well packed with bichloride gauze, secured by a firmly applied bandage. The horse-hair drainage is removed at the first dressing.

With glandular abscesses of the neck, simply opening the abscess and allowing the pus to escape is temporizing treatment; the cavity should always be curetted.

## MUSCULO-SPIRAL PARALYSIS COMPLICATING FRACTURE OF THE HUMERUS.\*

By FRANCIS W. MURRAY, M. D.,  
VISITING SURGEON TO ST. LUKE'S HOSPITAL.

THE UNCOMMON occurrence of the above complication, and also the desire to relate an interesting and successful case, are my reasons for bringing this subject to your attention. From the fact that fracture of the humerus occurs most frequently at the shaft, and from the intimate relation of the nerve to the bone in the musculo-spiral groove, it seems rather remarkable that the nerve so often escapes injury.

Bischoff,† in examinations on the cadaver, finds that the "dangerous place" (when the nerve lies on the bone) "begins about eleven centimetres above the external epicondyle of the humerus, and ends about six centimetres and a half above and behind." Thus the nerve is exposed to insult for only a proportionately short distance, and at this point it is also very firm and capable of resistance, all of which circumstances may explain its immunity from injury in cases of simple fracture of the shaft. In 562 cases of simple fracture of the humerus treated during the past twelve years at the Chambers Street Hospital, in New York, but three cases of musculo-spiral paralysis are to be found. Billroth, during a period of sixteen years in his clinic at Vienna, saw only three cases. From these individual experiences one naturally concludes that lesions of this par-

ticular nerve with fracture are rare, but it is only by collecting together all the material that a correct estimate of its frequency can be formed. Bruns,\* however, was the first to accomplish the collection and classification of the material, which had been accumulating for years, and his results are most interesting. He shows that while injury and compression of nerves in connection with fracture is of uncommon occurrence, still the complication is decidedly more frequent than has generally been supposed. He has collected the large number of 189 cases of nerve injuries with fractures, and all but 21 cases are simple fractures. Of the 189 cases, over two thirds (135 cases) were connected with nerves of the upper extremity, and of these 135 cases, 77 concerned the musculo-spiral nerve alone, and 2 cases involved the ulnar and median in addition. He found that the humerus was the bone most frequently complicated with nerve lesions, and the musculo-spiral the nerve most often concerned. Thus, in 101 cases of fracture of this bone attended with paralysis, there were 73 examples involving the musculo-spiral nerve. As to the seat of fracture, the lower and middle thirds were the most dangerous for this nerve, as shown by 4 times in the upper, 25 times in the middle, and 19 times in the lower third. Certainly these results show that the complication in question is not a rare one. Primary paralysis was more than twice as frequent (62 cases) as the secondary variety (25 cases), and of the former class the great majority (44 cases) were caused by contusion of the nerve, while in the secondary variety almost all cases were due to compression by callus and cicatricial tissue. Bruns's collection of cases ends with the year 1885, and in examining the literature since that year I have found the histories of only five cases. It is likely that I have failed to find some histories, but this is the result of a fairly faithful search with the assistance of the *Index Medicus*. The cases are briefly as follows:

Middeldorpf.† Man, aged thirty-two; caught in a thrashing machine, injuring his shoulder; paralysis set in immediately; seen seven weeks after accident. Complete musculo-spiral paralysis; also paresis of fibers of part of ulnar nerve and paralysis of deltoid muscle. Operation nine weeks after injury revealed fracture of surgical neck close to head of bone, lower fragment dislocated inward and backward and pressing on musculo-spiral nerve; fragment replaced; primary union of wound. Slight improvement began in a month, and paralysis cured at end of seven months.

Puzey.‡ Man, aged fifty; fracture in lower half of humerus; paralysis first noticed when splints were removed; excessive amount of callus. Operation three months after injury; nerve exposed over thickened bone; was pale, hard, and smaller than normal. It was dissected out of a groove for three or four inches, until free above and below. Some tingling at end of a week; improvement slow, but was cured at end of nine months.

Stimson.§ Young man; fracture of humerus about its

middle; treated usual way; did well, and was discharged with fracture cured. Afterward he returned with musculo-spiral paralysis; nerve exposed and found imbedded in callus, occupying a canal an inch long; above and below, it was free. Nerve liberated; wound healed kindly. Five weeks after operation slight movement of fingers, and at time of presentation before this society the restoration was complete.

Nicolson\* reports two cases. The first, a boy, aged ten; simple fracture at lower third of humerus; treated in right-angled splint; swelling of hand set in soon; six weeks after injury sloughing of ring and little fingers; paralysis discovered when splints were removed. Seen by Dr. Nicolson eighteen months after injury; wrist-drop well marked; flexor tendons contracted, and under ether inability to extend them; whole hand blue and cold; hyperæsthesia of palm of hand. Tenotomy to straighten wrist; electricity; some improvement. The second case was a girl, aged seven, fracture lower half of humerus; seen some months after injury; appearances same as in last case, excepting sloughing and hyperæsthesia of palm. Case had been treated by plaster splint, and there had been a superficial sloughing at center of forearm. In reporting these cases Dr. Nicolson mentioned a case occurring in the practice of Dr. Howell, of the same city. In a letter from Dr. Nicolson he states that his two cases disappeared and the ultimate results are unknown, and that Dr. Howell's case was one of immediate paralysis following fracture, and recovered without operation. He adds a third case lately seen in the practice of another physician, where the paralysis was complete, and attended with atrophy of extensors and supinators. The patient had lost the usefulness of the hand and forearm, as well as a large part of the hand by sloughing. Plaster splint was used in this case.

To these cases already briefly mentioned I should like to add the history of one lately under my care:

R. S., seven years of age, on March 25, 1891, was run over by a wagon and sustained a simple fracture of the humerus about the middle third. An ambulance surgeon reduced the fracture, applied a right-angled splint, and removed the boy to a hospital. That night the boy developed measles, and on the following day was removed to another institution. Here he remained about six weeks for treatment of the measles, and the fracture apparently received but little attention. On returning home, the splint was removed and the arm was found to be crooked, also loss of power in forearm and hand. On June 10th the boy came under my care at St. Luke's Hospital. Examination revealed well-marked deformity at the middle of right arm, a bowing outward and backward; and at this point was felt a prominence, evidently the upper extremity of lower fragment. Very little evidence of callus, no pain or crepitus, and a suspicion of false point of motion. Measuring both arms from acromion to olecranon shows a shortening of an inch and a quarter of right arm. Power of extension of forearm remains, but supination of forearm, extension of wrist, and radial flexion lost, "wrist-drop" marked, also impaired extension and abduction of thumb. Fingers flexed, but, on passive extension of proximal phalanges, extension of terminal phalanges is normal. Some atrophy of supinators and extensors, but they respond to

faradism; sensory disturbances slight. On June 13th incision two inches long on outer side of arm carried down to site of fracture, as nerve was not seen; the incision was carried downward and nerve exposed in its course between brachialis anticus and supinator longus muscles. On following the nerve up from this point, it was found firmly adherent to and tightly stretched over the edge of the lower fragment, which was dislocated upward and outward. At the point of compression the nerve was smaller, completely flattened out, and of a dark-red color, which extended a short distance above and below. Incision through periosteum, chisel inserted, and the edge of fragment removed; the nerve released and held to one side. On examination of fracture, the lower fragment was seen dislocated as mentioned, rotated strongly inward, and united to the upper fragment at an angle of 150°. I then refractured the arm by cutting through the callus with a chisel and straightening the member with my hands. Ends of fragments smoothed off with rongeur forceps and approximated with a strand of silkworm gut passing through holes drilled through the bone. Periosteum united by catgut, wound disinfected and united by a few deep and superficial catgut sutures. Sterilized dressing, plaster splint from wrist to axilla with few spica turns; forearm flexed on arm. Beyond slight suppuration in one or two superficial sutures, the wound healed kindly; splints removed in six weeks. Four weeks after operation there was some power of extension of fingers, and from that time his history is of steady improvement. Eight weeks after operation there was good use of arm, but not complete restoration. Late in September he returned to hospital with a small, fluctuating swelling over site of wound; incision let out a small amount of pus in which was found the silkworm gut. Wound soon healed, and he left with perfect and complete restoration of the right arm. On questioning the boy closely, I find that he was able to extend the hand and fingers immediately after the accident, and that the movements were not abolished until some time after his admission to the institution where he was treated for the measles. Four or five weeks elapsed before the fracture was examined, so it is fair to presume that the dislocation took place some time after the original application of splints. The case, therefore, is of some significance, as it is an example of compression of the nerve through secondary dislocation of a fragment, of which only few cases are on record. The refracture of the bone I think was proper under the circumstances, and without it the operation would have been incomplete. To have merely cut away the projecting end of the lower fragment would have relieved the pressure on the nerve, but the boy would have had a crooked and shortened arm, and, as he is right-handed, its usefulness would have been impaired. There are other points of interest in the case, but I will not detain you by referring to them. Through the kindness of Dr. L. A. Stimson I am able to add three other unrecorded cases, the cases mentioned above as occurring at the Chambers Street Hospital. They are briefly as follows:

CASE I. *April 29, 1885.*—G. T., aged forty-four years, simple fracture middle third of humerus. Shoulder cap and outside coaptation splints applied, but replaced in two days with plaster splint from wrist to axilla; spica at shoulder.

*July 17th.*—Paralysis noticed; wrist-drop marked; loss of sensation in fingers not absolute. Ordered electricity. Very slight improvement.

CASE II. *March 5, 1888.*—A. G., aged fifty years, simple oblique fracture middle third of humerus. Shoulder cap, apposition splints, elbow splint. Three days later, plaster splint wrist to shoulder.

*April 20th.*—Paralysis noticed. Faradism ordered. Result, improvement in extension at wrist and of fingers.

\* *Gaillard's Med. Jour.*, 1890, i, 20-24.

CASE III. *August 30, 1890.*—R. K., aged forty-four years, simple fracture middle third of humerus. Plaster splint from wrist to shoulder and spica.

*October 9th.*—Paralysis discovered, and, three days later, Dr. Stimson exposed nerve for three or four inches. It showed no signs of injury, and was not imbedded in callus or cicatrix. Union of fracture absolutely without deformity.

*November 13th.*—Wound healed, but no use in hand as yet. Result, last seen in September, 1891. Electricity and massage had been kept up in the mean time. The patient could raise wrist to level and was slowly improving. As to the ultimate results in the first two cases nothing is known, as they disappeared after the fractures were united.

The last case is unique in that the conditions revealed by exposure of nerve were not sufficient to account for the well-marked paralysis. The addition of the eleven cases collected in this paper to the number collected by Bruns makes ninety cases in all—certainly not a small number. Of this number, thirty-eight (forty-two per cent.) were treated by operation, and in almost all the nerve function was restored. While in thirty-four cases neurolysis was performed, in only three cases was the nerve sutured, showing the rarity of complete division of the nerve. Of the cases treated by neurolysis, the great majority (twenty-two cases) were examples of compression due to callus or cicatricial tissue; only seven were due to compression by a dislocated fragment. It is interesting to know that a large percentage were treated by operation, and that the results were mostly successful. Where paralysis is due to compression by callus, cicatricial tissue, or dislocated fragments, already consolidated, in my opinion the earlier the nerve is liberated the sooner will the patient be cured. Some authors advocate, however, waiting for months to see whether Nature will not effect a cure. Where the paralysis is due to the contusion of the nerve, and if no improvement appears in four to five months after the injury, I think exposure of the nerve is indicated. In such cases the nerve substance may be destroyed and replaced by fibrous tissue, which can be removed and nerve suture applied, or compression by a small fragment of callus or a fine band of cicatricial tissue may be found. A point worthy of mention in the performance of neurolysis is to expose the nerve, not at the point of compression, but rather at some distance above or below, and then follow it up to the desired spot. By so doing, one lessens the risk of injuring or cutting the nerve in our attempt to find it when enveloped in a mass of callus or cicatricial tissue. Finally, in the examination of every case of fracture of the humerus, it is wiser to look for any injury of the musculo-spiral nerve before applying the splints; otherwise the injury may be overlooked and not discovered until the appliances are removed, and it will then be impossible to say whether the paralysis was due to the injury or not. From a medico-legal standpoint it is also important in these days, when unscrupulous lawyers and ungrateful patients abound.

In conclusion, I would state that this paper has been prepared to show that musculo-spiral paralysis is not so infrequent in connection with simple fracture of the humerus, and also to place on record the case which came under my care.

## A CONTRIBUTION TO THE STUDY OF CEREBRAL TUMORS.

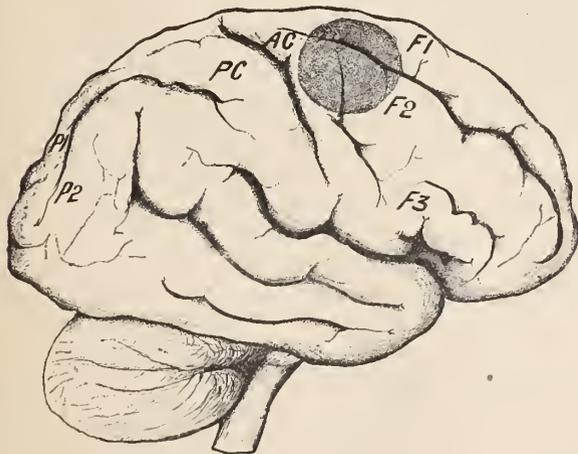

By P. C. BARKER, M. D.,  
MORRISTOWN, N. J.

A. W. B., a banker, aged sixty; always had good health, with the exception of two attacks of typhoid fever—one in early manhood, and the second while in the army in 1863. No specific history. In May, 1891, while asleep on a reclining chair one Sunday afternoon, he was observed to be breathing with difficulty—eyes opened and raised, arms and legs being drawn up and extended again. The seizure lasted but a few minutes, and he soon regained consciousness, assuring those around him that he felt perfectly well. It was not observed whether he was flushed or pale; nor were any other observations made than those mentioned. In July he fell while walking on the street. A physician chanced to be just behind him, saw him reel, and seized hold of him, but not soon enough to prevent a heavy fall to the pavement. It was not noticed which way he turned as he began to reel. He had an epileptoid convulsion, with the usual manifestations; was carried home and placed in bed. Some hours afterward, while lying quietly in bed, he had another convulsion—longer and more severe than that of the morning. I was summoned by telegraph, started at once for central New York, where he lived, and arrived there early the following morning. With the exception of some rather severe bruises about the face received by falling on the street the day before, he seemed to be as well as usual. In searching after any facts that might throw light upon the probable cause of these seizures, only the following were gleaned: In January, 1890, the patient lost his footing on an icy pavement and fell, striking on the back of his head. The pain was so severe that he was unable to get up for some time; and a persistent headache followed for several days. This accident was recalled by his daughter, and referred to after the investigation had continued for some time. The patient had entirely forgotten it, as he had had no symptoms remaining, beyond the few days mentioned, that suggested any connection with the fall. It also transpired that he had been unable to read evenings, as his habit formerly was, and that some member of the family had read to him for "a long time." He had consulted an oculist, and his trouble had been ascribed to the severe use his eyes had been subjected to during banking hours.

There were no more epileptoid attacks, and the patient attended to his usual duties until September without having special symptoms of any kind except an occasional feeling of weakness in his legs (as he said) and some unsteadiness in walking. At my request, his eyes were again examined, and, with the exception of slight astigmatism, pronounced normal. There was no optic neuritis. Late in September there was an attack of diarrhoea that lasted several days, together with anorexia, increased weakness, and unsteadiness. The urine became reduced in quantity one half, while the specific gravity fell from 1.023 to 1.006, where it remained for some days, and then gradually ran up to 1.016. Repeated tests failed to show the presence of albumin. The pulse was slow, temperature sub-normal every morning, and some days it remained all day a little below normal. The bowels were constipated, and he was troubled at times with dysuria and rectal tenesmus. Upon awaking in the morning, he was quite likely to have a little headache, which soon passed off.

These symptoms, as reported to me from day to day by the attending physician and the family, were very perplexing; and so, on October 23d, I visited him again. I got there before daylight and found the patient asleep. I soon noticed that the left

arm was never at rest for any length of time. The forearm would be extended upon the bed, and soon flexed again at intervals of a minute, more or less. Now and then he would rub his forehead and the top of his head with the right hand. After about an hour he awakened. The same restless motion of the left arm continued, but less often, and he occasionally passed his right hand over the head, as when asleep. Upon being asked why he rubbed his head, he replied that it felt bad when he first awakened after prolonged sleep: but it was hardly a pain. (Later on he did have some pain over the frontal region and vertex; but it was never severe.) He was not aware that he moved the left arm, and could give no reason for it. The tendon reflexes were practically normal. Sensation diminished in both arm and leg. Dynamometer showed a loss of one half in left hand. Left leg evidently weaker than the right. Percussion over the scalp was complained of when I finally came to the right parietal bone and over the anterior central region of the brain. Previous to this visit it had not been observed by the patient or any one else that his occasional shambling gait was unilateral; nor whether one hand rather than the other or both failed him in attempts at buttoning his collar; or other details in dressing. With these new facts it was at once manifest to me that the patient was suffering from a tumor (probably superficial) of the right anterior central region of the brain. The accompanying diagram was made at the time to indicate the probable location of the tumor, and was shown to the attending physician and to the family of the patient. Soon after this visit the symptoms became more pronounced. The arm and leg became more paretic, sensation more disturbed. At times both arm and leg would be almost devoid of sensation; at other times hyperaesthesia was complained of. At times, too, he would have mild transient delirium; or his face would be flushed, his nose cold and pinched, his pulse feeble, his respiration labored. One moment he would feel chilly and the next too warm. These varying symptoms were usually of short duration; and he would now and then have an entire day or entire night of continuous comfort. Then followed a more rapid progress, the leg and arm becoming entirely paralyzed, pulse and respiration greatly increased in frequency, increasing hebetude, coma, and death—six months after the first convulsion.

*Post-mortem.*—Body somewhat emaciated, rigor mortis well marked. Superficial sinuses congested. Dura mater rather opaque, but otherwise of normal appearance. Brain and membranes removed intact. Upon section of the dura mater, a tumor two inches and a half in diameter was found in the exact spot indicated in the diagram. The dura mater was firmly adherent to the center of the growth, involving an area of a little

less than an inch. There was a nucleus of corresponding size that was readily lifted out from the rest of the neoplasm, which presented an entirely different appearance from the latter in color and general appearance, being whiter and of closer, firmer texture. Next to this nucleus, upon all sides and beneath it to a depth also of nearly two inches and a half, was, first, a highly vascular area, with many small extravasated blood clots, while beyond this was an area of yellowish, semi-softened tissue that gradually changed into healthy-looking white matter. Upon the vertex of both hemispheres the arachnoid was opalescent, and there was also an effusion beneath it. Only a hasty examination of the deeper structures was made, as none of the observed symptoms remained unexplained, and nothing else abnormal was noticed. Professor Prudden examined the nucleus mentioned and reported that it was a spindle-celled sarcoma.

It is extremely probable that the fall was responsible for this growth. I was unable to determine whether the original growth started from the dura or from the gray matter beneath it. The bond of union between the dura and the nucleus was certainly very firm, but it was separated with the handle of the scalpel, although with some difficulty.

The period that elapsed between the fall and the first epileptoid seizure—about sixteen months—not only sufficed for the growth of the nucleus, but for the second stage as well, the period characterized by the epileptoid convulsions and due to the multiple hæmorrhages. During the first period no impairment of health—no symptoms of any kind save possibly one—were experienced by the patient. His inability to use his eyes as he had been accustomed to use them may have been due to the growth, by involvement of communicating fibers between this region and the inferior anterior frontal region. The third stage, that of softening, was prolific in symptoms and disturbances.

#### REPORT OF A PECULIAR CASE OF CHRONIC ASCENDING POLIOMYELITIS ANTERIOR.\*

By CHARLES E. LOCKWOOD, M. D.,

NEW YORK,  
ATTENDING PHYSICIAN, DISEASES OF THE NERVES,  
OUTDOOR POOR DEPARTMENT, BELLEVUE HOSPITAL.

Mrs. A., white, aged forty-six, born in Ireland.

*Family History.*—Father died of old age; mother died of cancer of the breast, aged sixty-six years; three sisters and one brother living and well; one sister died of consumption, aged twenty-two years.

*Personal History.*—Never seriously ill; has suffered somewhat at times from malaria. In the spring of 1889 she had a sharp, shooting, burning pain in the right foot, but did not consult a physician in regard to it. She spent the summer of 1889 in Saratoga, and thinks the place where she lived was damp. No history of gout, rheumatism, or syphilis. On September 1, 1889, she stumbled over a chain, bruising her right shin slightly, and a few days afterward noticed that she was unable to walk as well as formerly. The trouble persisting, she consulted me, February 6, 1890, complaining of a peculiar heaviness and weakness of the right leg and foot in walking, and of a diminution of the temperature in these parts. On examination, I discovered marked weakness of the flexors of the foot and the ex-

\* Read before the Medical Society of the State of New York at its eighty-sixth annual meeting.

tensors of the toes. The right leg and foot felt colder to the touch than the left; atrophy of the anterior tibial muscles was not marked. There was no pain; no sensory, rectal, or bladder disturbances. Tendon reflex at the right knee was present. There was diminished electro-muscular excitability to the induced current, and the normal formula was practically unchanged so far as galvanism was concerned. Here, then, was a case characterized by a marked loss of power in the group of muscles supplied by the anterior tibial nerve, coming on insidiously and gradually, with no premonitory symptom, except the shooting, burning pain in the right foot, noticed during the preceding spring. No appreciable atrophy; no sensory, bladder, or rectal disturbance. Tendon reflex at the knee intact; reaction to the faradaic current diminished, and to the galvanic unaltered. The temperature of the affected limb lower subjectively and objectively, and this condition connected in its apparent commencement with a local injury in the mind of the patient, who otherwise appeared to be in a good state of health. Was the affection central or peripheral? I was unable to decide, and asked Dr. Allan McLane Hamilton to see the case. He expressed the opinion that the trouble was not central, and advised the application of the actual cautery over the peroneal nerve near the outer tendon of the biceps muscle, the hypodermic injection of the paralyzed muscles with one sixtieth of a grain of strychnine daily, massage, and the daily application of the faradaic current. In the way of medication, fifteen grains of salicylate of sodium three times a day, and two teaspoonfuls of Fellows's hypophosphites with meals. Prognosis was that the patient would eventually recover, but convalescence would be tedious. Such was the treatment pursued without improvement until March 31, 1890, when, while going into church, the patient's right leg gave way, and she fell, bruising her face severely.

On April 1, 1890, my patient was seen by Dr. M. Allen Starr, who found paralysis of the anterior tibial group of muscles of the right leg, atrophy, and the reaction of degeneration; loss of faradaic reaction and change in the galvanic reaction, with the knee-jerk still preserved.

*Diagnosis* was degeneration of the nerve, with impaired sensation and motion; said it would take a year to recover, and recommended the use of the continued and interrupted galvanic currents—one pole over the sciatic nerve and the other over the anterior tibial muscles two or three times a week—massage, and the wearing of a shoe with a piece of iron in the sole connected with an upright piece fastened to the leg by a leather band to prevent foot-drop. About the middle of April the patient complained of a sharp, shooting pain in the left foot, the same in character as that felt in the right foot a year before, and further treatment was prevented by her departure to the country for the summer. On her return in October, 1890, examination by Dr. M. Allen Starr and myself showed complete paralysis of the entire right leg, with reaction of degeneration, loss of power and electrical contractility of the anterior tibial muscles of the left leg, and atrophy and loss of power of the thenar and hypothenar muscles of the right hand, with fibrillary twitchings and diminished faradaic excitability. A diagnosis was now made of chronic ascending poliomyelitis anterior, lesion having given effects first in the peroneal muscles of the right leg.

The treatment decided upon was ten drops of Thompson's solution of phosphorus after meals for two weeks, and then one sixtieth of a grain of strychnine and one fortieth of a grain of arsenious acid, three times a day for two weeks; and their use afterward alternately for two weeks. The application of the faradaic current to the affected muscles half an hour daily, massage, and dry cups to the spine weekly.

The above treatment was followed for about a month, when

patient showing no improvement, but gradually growing worse, her friends were anxious to have another opinion on the case, and Dr. G. M. Hammond saw her and concurred in the diagnosis of chronic anterior poliomyelitis. He was able at that

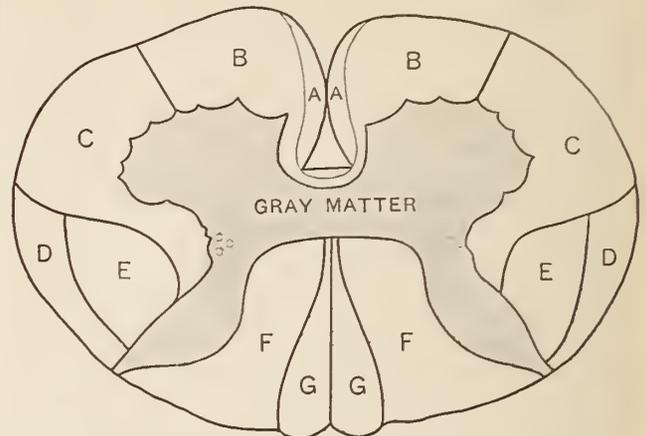

Diagram of section of the cord through the lower part of the cervical enlargement (Ranney). A, uncrossed pyramidal tract or column of Türk; B, anterior columns; C, lateral columns; D, direct tract from lateral column to cerebellum; E, crossed pyramidal tracts of lateral column; F, columns of Burdach or posterior root-zone of Charcot; G, column of Goll; site of lesion, B, C, E, and portions of gray matter.

time, over one year from the commencement of the disease, to obtain slight tendon reflex on the right knee, better and fair on the left knee; found sensation good; atrophy of muscles on inner sides of lower parts of thighs; atrophy of legs not marked; gastrocnemii contracted. Dr. Hammond gave a favorable prognosis; he thought the patient could be cured, but it would take a long time. He advised the use of the fluid extract of ergot, one teaspoonful three times a day after meals, to prevent congestion of the cord, and iodide of potassium, commencing with ten grains well diluted, three times a day after eating, and increasing the dose daily by one grain until the dose of sixty grains three times a day was reached, to prevent the formation of connective tissue, and the use of the galvanic current on the affected muscles daily.

The patient at this time was placed under the care of Dr. Hammond, and he very kindly informs me that "she subsequently died at the Post-graduate Hospital, about two years after the commencement of the disease, from the extension of the degeneration upward until the medulla was reached and the cardiac and respiratory centers were implicated. About a week before she died she began to complain of shortness of breath; there was also a slight degree of cardiac irregularity. These symptoms were intermittent. At the end of the week she suddenly had an attack of cardiac and respiratory paralysis; she was treated by hypodermic injections of strophanthus, digitalis, and whisky, and rallied. In about two hours she had another attack; remedies were unavailing, and she died."

A post-mortem examination was made by Dr. G. M. Hammond, and sections of the spinal cord from the dorsal and upper lumbar regions were made for microscopical examination by Dr. Edward K. Dunham, of the Carnegie Laboratory, who describes the conditions found as follows: "In sections of the spinal cord which you submitted to me for microscopic examination the posterior columns of the white matter appear normal.

"In the crossed pyramidal tracts on both sides the number of nerve fibers is decreased and the amount of interstitial tissue increased—descending degeneration. The number of nerve fibers in the rest of the antero-lateral columns of the white substance also appears to be diminished with an increase of inter-

stitial tissue, but the amount of the change is not as great as in the crossed pyramidal tracts.

"In the gray matter the walls of the blood-vessels are considerably thickened, and I have thought that some of the nerve cells in the anterior cornua were atrophied, but there are so few normally present in this portion of the cord (dorsal and upper lumbar) that I have not been able to satisfy myself upon this point. The examination of other portions of the cord would be of interest as showing whether the changes in the antero-lateral columns of the white matter were a part of a disseminated sclerosis, and also the cause of the descending degeneration in the crossed pyramidal tracts."

March 1, 1892.—Dr. G. M. Hammond, having made sections and microscopic examinations of other portions of the spinal cord, has kindly furnished the following description of conditions found: "Sections of the lower medulla show the hypoglossal nucleus to be normal. The motor cells of the pneumogastric nucleus are atrophied, also the spinal accessory cells. Respiratory bundle, just beneath the pneumogastric center, shows slight evidence of sclerosis. Anterior pyramids show slight sclerosis; all else seems normal. The cervical cord shows same lesions as those found in the dorsal and upper lumbar portions heretofore described."

The points of special interest in this case seem to me to be:

1. The rarity of this form of the disease, Erb having stated, in 1876, that only two reports of post-mortems were then on record.

2. That the apparent commencement of the disease seemed to be associated with a local injury, thus suggesting a peripheral cause for the paralysis.

3. The difficulty experienced in making an early diagnosis, owing to the fact that *those muscles only* of the right leg were primarily affected which were supplied by the anterior tibial nerve, thus seeming to point to a peripheral lesion.

4. The slow progress of the disease upward, its effects for six months being confined to the anterior tibial group of muscles, and its entire progress occupying two years.

5. The advisability of taking into consideration the possibility of the existence of chronic anterior poliomyelitis in a slowly progressing motor paralysis of a group of muscles supplied by a single nerve with no sensory disturbances.

6. The impossibility of distinguishing between a central and a peripheral cause, while the effects of the disease were manifested in the peroneal muscles only, by means of the electrical reactions, as the reaction of degeneration might be present in both instances.

7. The possibility that the trouble may have been primarily peripheral and secondarily central.

8. The persistence of the cathode closure contraction to the last, as observed by Dr. Hammond.

9. The identity of this case with those described by Charcot, Marie, and Tooth as the peroneal type of progressive muscular atrophies, concerning which Dr. Putzel, in Wood's *Reference Hand-book of the Medical Sciences*, says: "Hardly anything is known concerning the pathological anatomy of the peroneal type of progressive muscular atrophies. Charcot and Marie suggest that it is the result of peripheral neuritis, and in three cases interstitial neuritis was found on autopsy. It must be admitted, how-

ever, that our knowledge of this affection is too imperfect to warrant us for the present in drawing any conclusions with regard to its pathology and pathological anatomy," and under the heading of Pathology he remarks: "The nature of the lesion in the peroneal type of muscular atrophy must be left for future investigations; we may say, however, that the strong hereditary element and the clinical history seem to indicate a peripheral rather than a central origin."

## AN ANCIENT SPA.

BY FREDERICK PETERSON, M. D.

THE Baths of Helwán, in Egypt, perhaps merit the distinction of being the oldest health resort of the world, and while their situation in so remote a country as Egypt may not make a reference to them so valuable to American physicians as it otherwise might be, still it may have a historical interest to many of your readers, and a few may find some practical use in the following notes of a recent visit, for the travel of American invalids in this direction is becoming greater year by year.

While I have spoken of the Helwán springs as the most ancient spa of the world, their early history is somewhat obscure. It seems reasonably certain, however, that during the eighteenth dynasty, or something over thirty-five hundred years ago, King Amenhotep sent persons afflicted with leprosy and other incurable diseases to these springs for treatment. There are perfectly authentic records of their being a health resort twelve hundred years ago, but from that time until a very recent period they had a very precarious existence, as the various layers of bricks, granite, marble, pottery, and the like found as ruins of ancient villages would seem to indicate. Somewhere about 1871 the Egyptian Government inaugurated a new era for these springs by reconstructing the baths, building a hotel, planting trees and the like, so that now a pleasant, well-built town, with palm groves and villas, and a good railway from Cairo, stands where not long ago was but a waste of yellow sand.

Helwán is said by some to derive its name from the Arabic word *helwa*, meaning sweet; but this would hardly be suggested by the waters, which are particularly generous of their exhalations of sulphureted hydrogen. The modern spa lies fifteen miles south of Cairo in the desert, about three miles from the Nile, and with about two miles of sand intervening between it and the river. Back of it lie the barren, fantastic, and precipitous cliffs of Mokattam. It may be classed with the desert health resorts, and as such is the most accessible of all, while it partakes of that remarkable dryness and purity of air common to such situations. Its elevation is some 112 feet above the level of the Nile. Thus far about a dozen springs have been rediscovered. They are all thermal, varying in temperature from 77° to 86° F., but they differ in their chemical constitution, for some are sulphurous and others chalybeate and saline. The analyses made of most of them are as follows:

*Three Sulphur Springs.*—Temperature, 86° F.; sp. gr., 1.0025.

The chalybeate water is chiefly used for its aperient, and the saline for its purgative effects. Both are odorless and colorless. The hot sulphur springs are those which enjoy the greatest repute and are most valuable. As soon as one enters the town their odor becomes apparent. The sulphur in the air turns silver ornaments black. The water of the springs is at first quite clear, but upon exposure to the

air becomes covered with a film of sulphur and lime salts, and a greenish cryptogam, called barégine (from the Baréges waters of the Pyrenees), develops in it.

The bath-houses are commodious and luxurious, kept in good order, and are indeed up to the usual standard of similar institutions in the better-known health resorts. The water is artificially heated to higher temperatures when required. A European physician is in charge of the establishment, and European physicians are numerous in Cairo, near at hand. The two hotels and furnished and unfurnished villas to let afford excellent accommodations for invalids.

The diseases for which these baths are indicated are pre-eminently rheumatism and certain skin disorders, and, in conjunction with the natural advantages of such springs the world over, the incomparable winter climate of Egypt is to be considered. There is almost never rain or cloud or fog, and the mean annual humidity is certainly less than that of Cairo, which is 58·4 (Greenwich 87, Algiers and New York 70). The isothermal line runs between Florida and Canton and Algiers and Santa Cruz.

Dr. Sandwith, of Cairo, summarized the monthly bulletins of the Khedivial Observatory for five years, finding the average annual rainfall to be 1·22 inches.

While we in America make comparatively little use of foreign thermal springs, still, many of our patients go to Aix-les-Bains, the springs of which are about the same in character as those of Helwán, and Aix, as well as our own Hot Springs, is in a much colder latitude than these Egyptian waters—a matter of a great deal of importance, even if the distance be great.

It is needless to say, too, that the mind has more to occupy it here than in most health resorts, for, in addition to the pleasures common to all such places—such as social diversions, riding, driving, and reading—there lie in plain view across the river the Pyramids and the mounds of ancient Memphis. The modern Egyptians are interesting in their manners and customs. The great quarries of Toura and Maaserah, from which the stones of the Pyramids were taken, are near at hand. The desert is spread all around, and, even if one be not a geologist with an eye to the innumerable fossils of the nummulitic hills, or a naturalist zealous for novel additions to his collections, or an amateur astronomer eager to gaze upon a wide and brilliant expanse of starry heaven, the desert, like the sea, possesses a fascination of its own which it is difficult to define, or impress upon another with empty words.

HELWÁN, EGYPT, January 20, 1892.

**Spontaneous Cure of a Severe Abdominal Wound.**—Dr. Schildt mentions in *Duodecim*, a Finnish medical journal, a case, showing that, occasionally at least, a large wound into a serous cavity which looks hopeless enough may heal without treatment. He was called some years ago to a poor man supported by charity, who, in consequence of inflammation of the groin, had a large gaping wound of the abdominal wall, through which some six inches of the small intestine protruded, all covered with blood, added to which there was a discharge of fœtid matter. The man was sent to the hospital, where, however, he could not be admitted, as all the beds were full. He was therefore taken home again, and received no treatment whatever. Nevertheless, Dr. Schildt a short time ago happened to see him alive and well, the wound having healed spontaneously.—*Lancet*.

## TYPHILITIC ULCER.

PERFORATION; OPERATION; RECOVERY.\*

By FRANK HARTLEY, M. D.

WHEN one considers that in 324 cases of the so-called perityphlitis collected from various authors, 282 times the appendix was found to be the seat of the disease, the importance of the appendix as a starting-point for disease and the frequency of its involvement can not be disputed.

Other conditions exist in the right iliac fossa, however, which, though not so frequent, demand quite as much interest both in a diagnostic and curative sense.

My interest in these conditions has been largely due to two autopsies upon cases operated upon for appendicitis.

In one case the symptoms—such as the exact spot for the pain, the tympanites, intumescence, resistance, temperature, and respiration, without a distinct history of previous troubles—pointed to appendicitis. The autopsy revealed an ulcer of the sigmoid flexure, progressive peritonitis occupying the lower half of the abdomen, with a single localized interintestinal abscess below and upon the inner side of the cæcum.

The appendix was normal, about four inches in length, and lay upon the inner side of the cæcum and ascending colon.

In the second case, in which there existed a suppurative salpingitis, with circumscribed suppurative peritonitis and with adhesion of the vermiform process to the abscess, the lateral laparotomy was performed for a suppurative appendicitis. The imperfect history given by the patient and the failure to make a vaginal examination apparently misled the operator.

Such cases as the above must impress us all with the importance of a careful physical examination and distinct anamnesis. While appendicitis, suppurative or gangrenous, is often the cause of a localized or diffuse peritonitis, ulceration in the cæcum in the neighborhood of the appendix may give rise to a condition quite similar in its local manifestation. Such a case was reported by Dr. W. Ela, of Cambridge, Mass., in December, 1889, in which recovery followed the operation.

The patient I show to-night is one on whom I operated for typhlo-enteric ulceration with success.

The history is as follows:

J. B., aged forty-seven, Switzerland, painter, was admitted to the Roosevelt Hospital August 2, 1891. Family history is good.

*Personal History.*—Until twenty-two years of age he was perfectly healthy. At the age of twenty-two he had an attack of gonorrhœa. At twenty-six he had rheumatism. At thirty years of age a second attack of gonorrhœa. From thirty to thirty-six he had two attacks of gonorrhœa, with one of which he acquired chaneroids upon the glans penis, with inguinal adenitis. From the twenty-second to the forty-second year of age he had about five diarrhœal movements daily. During the summer these movements became less, and increased in number during the winter. Since the forty-second year of age he has had but one movement daily. This had been always of a watery character.

The present trouble existed for two weeks. At the begin-

ning of this trouble he suffered from general abdominal pain which he could not localize in any particular region of the abdomen, and which supervened upon a hearty meal. It finally involved the whole abdomen until, after taking a dose of castor oil, on the second day, the pain over the abdomen was relieved. This pain disappeared completely during the next twenty-four hours, except for a distinctly localized spot in the right iliac fossa. He has never vomited and has had daily movements.

*Examination.*—Patient is a weak, ill-nourished man; pulse, 120; temperature, 102°. His face shows a marked sepsis. Respiration: thoracic, superficial, and about thirty per minute. Lungs and heart normal. Urine, 1·020, no casts, few pus cells, albumin a trace, otherwise normal. There is a swelling in the right iliac fossa; it can be indistinctly defined. There is slight general tympanites present. The situation of the greatest resistance and tumefaction is just below a line drawn from the umbilicus to the anterior superior spine of the ilium. The abdomen at this point is tender, and the point of greatest tenderness is a finger's breadth below the aforesaid line, and at the outer border of the rectus muscle. Rectal examination reveals nothing, and the examination of abdominal viscera is also negative.

*Diagnosis.*—Ulcer of the intestine with abscess, so far encapsulated, probably typhlo-enteric.

*Operation.*—Antisepsis; ether; incision; as for the appendix (lateral laparotomy), on approaching the peritonæum the tissues were found very œdematous. The peritonæum was incised and the tumor was entered. It contained pus in large quantity. The odor was feculent. The walls of the abscess cavity within the peritoneal cavity were very thick, composed of successive layers of fibrin and lined throughout with granulation tissue. The wall of this cavity was formed by the lymph covering the caput coli, small intestines, and the peritonæum over the iliac fossa. The vermiform appendix was found uninvolved and forming a part of the wall of this cavity. On the caput coli to the inner side of the base of the vermiform appendix was found a perforation large enough to admit the forefinger. Its edges were ragged, irregular, and seemed somewhat indurated. The vermiform appendix was ligated and taken away. An examination of it revealed its normal condition. The perforation in the cæcum, through which fœces escaped, was excised. The edges were inverted and sutured with fine silk (Czerny-Lembert). Disinfection of the cavity. Iodoform gauze tampon. Abdominal wall sutured in the upper two thirds of its extent. Lower third was left open.

Temperature, 99°; pulse, 100, on third day.

Dressed on the fifth day, and packing of iodoform removed. Gauze replaced.

The patient continued to improve and was discharged five weeks later, completely cured.

*Sources of Syphilitic Infection.*—“Dr. Rassler, in his essay for the M. D. of the University of Kiel, makes a valuable contribution to the literature of syphilitic disease. The *Archiv für Dermatologie und Syphilis* states that Dr. Rassler undertook the labor of analyzing six hundred and thirty cases of syphilis treated in the medical clinic with the object of ascertaining the number arising from extra-genital infection. He found thirty-four such cases, comprising twenty-three of the lips, one of the tongue, two of the mucous membrane of the mouth, and three of the mamma. In three instances the primary sore occurred on the genital organs without connection having taken place, and in the remaining two it was impossible to indicate the locality. The result of these investigations shows that five per cent. of all cases of syphilis are due to extra-genital infection. According to other authorities, the proportion varies between one and ten per cent., except in certain parts of Russia, where the proportion is said to reach as high as eighty or ninety per cent.”—*Lancet*.

## MULTIPLE FRACTURE OF THE STERNUM,

FOLLOWED BY NECROSIS AND ABSCESS.

REMOVAL OF THE FRAGMENT, WITH RECOVERY.

By JOHN R. HINKSON, M. D.,

BLISSVILLE, LONG ISLAND CITY, N. Y.

Miss D., aged fourteen, was seen by the writer on September 7, 1891. She was then suffering great pain, had a hectic flush, and a temperature of 101.5° F.; she also had a pulsating tumor, about the size of a goose's egg, situated in front of the sternum on a level with the third, fourth, and fifth ribs, in which fluctuation could be plainly detected, the skin covering the tumor being normal in appearance. The left breast was considerably swollen and excessively tender.

It was at first thought that the case was one of empyema which had ruptured beneath the skin; but, on examination of the posterior aspect of the chest, there were no abnormal physical signs discovered, nor was there any bruit to be heard in the tumor, and the pulsation was not expansile.

The diagnosis of an abscess was made, and was confirmed by an exploratory puncture with a hypodermic needle.

The following is the history of the case given by the girl's mother: Some time in the latter part of March, 1891, a boy, aged fourteen, struck her a violent blow in the chest; she was able to walk to her home, which was but a very short distance away, but was subsequently troubled with frequent attacks of syncope and constant "pain in her heart." A physician was called in, and he attributed her symptoms to the advent of menstruation, she never having menstruated up to this time. Menstruation occurred, but brought no relief, and another physician was consulted, who stated at first that the patient was suffering from remittent fever, but when the tumor in front of the sternum became more prominent, he said it was an aneurysm, and that recovery was hopeless.

The latter physician was in attendance on the patient for eight days before she was seen by the writer.

On September 8, 1891, the patient having been anesthetized, an incision was first made in the tumor over the sternum, allowing a large quantity of pus to escape; a uterine dressing forceps was next introduced as a director, when the abscess cavity was found to extend as far to the left as the posterior axillary line, and as low down as the sixth rib, being limited above by the clavicle; it was also superficial to the pectoral muscles.

An incision two inches long was made about the junction of the third rib with the posterior axillary line, parallel with the long thoracic artery, and the cavity was washed out with a 1-to-10,000 solution of mercuric chloride. A pocket was also found extending from the middle of the second piece of the sternum upward and to the right for a distance of three inches; into this a finger was inserted and an incision an inch long was made at its upper extremity.

On further examination, the sternum was found to be fractured transversely at the level of the fourth rib, and it was determined to wire the fragments. With this intention the first incision was enlarged and a plain retractor inserted between the pericardium and the upper fragment, in which two holes were drilled and wires passed through. The lower fragment was about to be treated in like manner, but, on raising it with the retractor, it was found to be quite movable; the incision was prolonged downward, and a second transverse fracture was discovered at the junction of the sternum with the rib below.

As there was no attachment of periosteum to the intervening piece of bone, it was removed, the abscess cavity was again washed out with a solution of mercuric chloride (1 to 5,000)

and a large drainage-tube passed from the opening on the right side through the abscess cavity to the opening on the left side. The incision in front of the sternum, which was four inches long, was closed with sutures of wire, leaving an opening an inch and a half in extent opposite the place where the loose fragment was removed. Into this opening iodoform gauze was packed in order that healing should take place by granulation from the bottom. The severe oozing which occurred at this situation was checked by the application of pure carbolic acid.

The patient did not bear the operation at all well, and great difficulty was experienced in resuscitating her from the ether narcosis. At the close of the operation the radial pulse was found to be extinct and the facial barely perceptible; the respirations had also become very infrequent. Hypodermic injections of whisky and atropine were administered, but without effect. Nitroglycerin, one one-hundredth of a grain, hypodermically, was then tried, and in less than five minutes the pulse was felt at the wrist, the patient becoming conscious a few minutes later.

The dressing was composed of iodoform and corrosive sublimate gauze, over which was placed a thick layer of absorbent cotton.

*September 11th.*—The dressing, which had become quite moist and had an offensive odor, was changed. The sutures in the upper portion of the wound were found to have cut through, and were therefore removed. The abscess cavity was irrigated with a solution of mercuric chloride (1 to 5,000) and the patient dressed as on the former occasion. Pulse and temperature approximately normal, the patient having complained of little pain since the operation.

*15th.*—The sutures in the lower part of the wound, which was now completely healed, were removed. The drainage-tube was also removed and the abscess cavity irrigated with a solution of mercuric chloride (1 to 5,000). Dressing as before.

After this date the dressing was changed twice a week. The wounds healed very slowly, the incision on the left side of the chest not having cicatrized till one month, and that on the right side not till two months after the operation. The wound in the median line was not found to be completely healed till January 3, 1892.

The patient is now in excellent physical condition, and experiences no pain or inconvenience whatever on account of the absence of the portion of the sternum removed.

**The Prevention of Rabies.**—"Were it not that experience has fully proved, both in England and on the Continent, the efficiency of the muzzle as a preventive of the spread of hydrophobia, we might excuse the delusion that the disease lately so prevalent in this country has died a natural death. The facts mentioned in the *Lancet* of April 5, 1890, however, show too close a connection between the prophylactic method and its effect to admit of any real doubt upon the subject. The past year has been a period of probation. The immunity conferred by the muzzling order has not, perhaps, unnaturally been taken as justifying its discontinuance in favor of the less irksome system of collar registration, and so far, there is every reason to believe, with fairly satisfactory results. In this way such cases of rabies, at least, as arise among stray dogs, and they comprise the greater number, should, if the regulations are stringently enforced, be held in check. Of the efficiency of the muzzling system and the justice of its application two years ago, we can not entertain a doubt. In its absence registration is and must remain for some time to come quite indispensable. It is difficult indeed to see how, without some such preventive arrangement, security against the disease can be relied upon. We trust, moreover, that on the least sign of a recrudescence of the disease, in the interest of our faithful friends, the dogs, as well as of the human race, muzzling may again be strictly enforced."—*Lancet*.

THE AXIS OF ASTIGMATIC GLASSES.\*

By JOHN HERBERT CLAIBORNE, M. D.,  
NEW YORK.

In presenting this paper I have little hope of adding new facts to your knowledge, but I do hope to make its purpose and its contents clear. The initial proposition which I wish to make is that astigmatism does not occur at hap-hazard, that there is a regularity in its occurrence in a given eye, and that there is a certain definite relationship between the axes of the astigmatism in the two eyes when both happen to be astigmatic. In order that I may plunge into the midst of my subject, permit me, without more ado, to take up the consideration of the axis of astigmatic glasses in the various forms of astigmatism *seriatim*. In using the expression axis of astigmatism, I use it synonymously with the axis of the cylindrical glass that corrects the error.

1. *Simple Hyperopic Astigmatism in a Single Eye.*—In the majority of cases the axis of this form of astigmatism is vertical—that is,  $90^\circ$ . If a deviation from this position takes place, it must be in the direction of the horizontal axis on either of the two sides of the vertical axis, and the first position assumed by such a deviation is the axis  $75^\circ$  or the axis  $105^\circ$ , which is a deviation of  $15^\circ$  from the vertical position. The next axis of preference is either  $135^\circ$  on the one side or  $45^\circ$  on the other side of the vertical. It is certainly comparatively rare that the axis of simple hyperopic astigmatism is horizontal, nevertheless it does occur. Now, the point which I wish to emphasize is that these five positions—viz.,  $90^\circ$ ,  $105^\circ$ ,  $135^\circ$ ,  $75^\circ$ ,  $45^\circ$ —are the positions of preference for hyperopic astigmatism. It may not be altogether wise at this date to state it as my opinion that any of the axes lying between these points are not selected by hyperopic astigmatism, but I feel compelled to do so from a sense of profound conviction. I believe that when any other axes than those mentioned are found, the axes have been the exceptions that prove the rule or have been incorrectly diagnosed. The following are the possible individual positions of the axes in simple hyperopic astigmatism in a single eye:

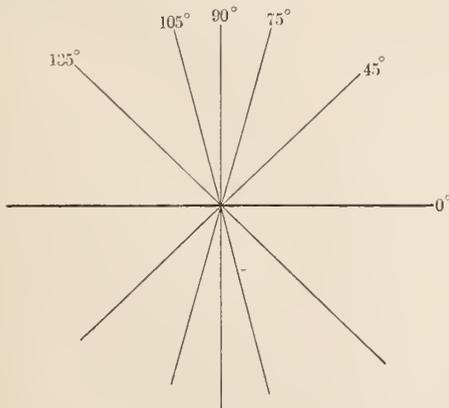

Fig. 1.

The realm proper of hyperopic astigmatism may then be said to extend  $45^\circ$  on either side of the vertical. In

\* Read before the Section in Ophthalmology of the New York Academy of Medicine, February 15, 1892.

other words, it may be said to include  $90^\circ$ , or one quarter of the circle; and of the axes included within this realm, the five axes— $90^\circ$ ,  $105^\circ$ ,  $135^\circ$ ,  $75^\circ$ ,  $45^\circ$ —are the axes of preference. The axis 0 occurs as stated by exception.

II. *Simple Myopic Astigmatism in a Single Eye.*—The axis of simple myopic astigmatism is in the large majority of cases horizontal. If, now, the eye select a deviation from this axis, it selects the axis that is  $15^\circ$  from the horizontal on the one side or the other; in other words, the axis  $165^\circ$  or the axis  $15^\circ$  is chosen. I have not had a case in which the axis of simple myopic astigmatism has not been one of these three positions, unless it were vertical. I have found this latter erratic axis quite frequently in myopic astigmatism; it is more frequent to find this than it is to find the axis of hyperopic astigmatism in the horizontal position. The following are the possible individual positions of the axes in simple myopic astigmatism in a single eye:

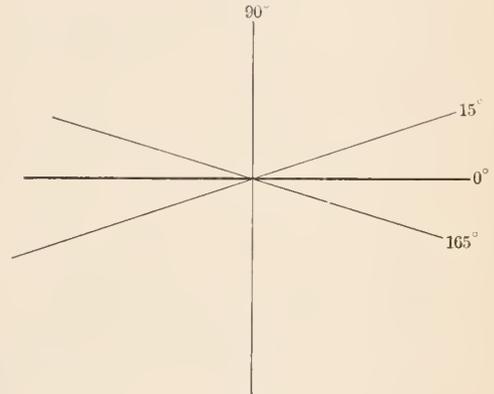

Fig. 2.

Its realm proper may then be said to include  $30^\circ$ , or one third of a quarter of the circle, and the axes included within this realm— $180^\circ$ ,  $15^\circ$ ,  $165^\circ$ —are the axes of preference. The axis  $90^\circ$  occurs as stated by exception.

III. *Compound Hyperopic Astigmatism in a Single Eye.*—Statements which have been made with regard to the axis in simple hyperopic astigmatism I hold to obtain in compound hyperopic astigmatism, for compound hyperopic astigmatism is simple hyperopic astigmatism coupled with spherical hyperopia.

IV. *Compound Myopic Astigmatism in a Single Eye.*—The axes of compound myopic astigmatism are the axes of simple myopic astigmatism.

V. *The Axes of Mixed Astigmatism in a Single Eye.*—It may be broadly said in the beginning that the above rules in regard to hyperopic astigmatism and myopic astigmatism hold when these two conditions occur in the same eye. The axis of the hyperopic astigmatism is restricted, as a rule, to the realm marked out for this error and to the axes of preference in this realm—viz.,  $90^\circ$ ,  $75^\circ$ ,  $45^\circ$ ,  $105^\circ$ ,  $135^\circ$ . The axis of the myopic astigmatism is restricted to its realm proper and to the axes of preference contained therein, as long as that is permitted by the axis of the hyperopic astigmatism. For example, if the hyperopic axis be vertical, the myopic axis will be horizontal. If the hyperopic axis be  $105^\circ$ , the myopic axis will be  $15^\circ$ , or at a right angle. If the hyperopic axis conversely be  $75^\circ$ , the

myopic axis will be  $165^\circ$ . If, however, the hyperopic axis be cast as far from the vertical as  $45^\circ$  or  $135^\circ$ , the myopic axis will be forced from its realm proper and will be compelled to invade the realm of the hyperopic axis. For example, if the hyperopic axis be found to lie at  $45^\circ$ , the myopic axis will be found to lie at a right angle—viz.,  $135^\circ$ , or *vice versa*. It occurs sometimes, though rarely, that mixed astigmatism is found in an eye with each axis in a position the reverse of the most usual one; for example, with the hyperopic axis horizontal and the myopic axis vertical. I have seen this in one eye, but never in both.

The following are the possible individual positions of the axes in mixed astigmatism in a single eye:

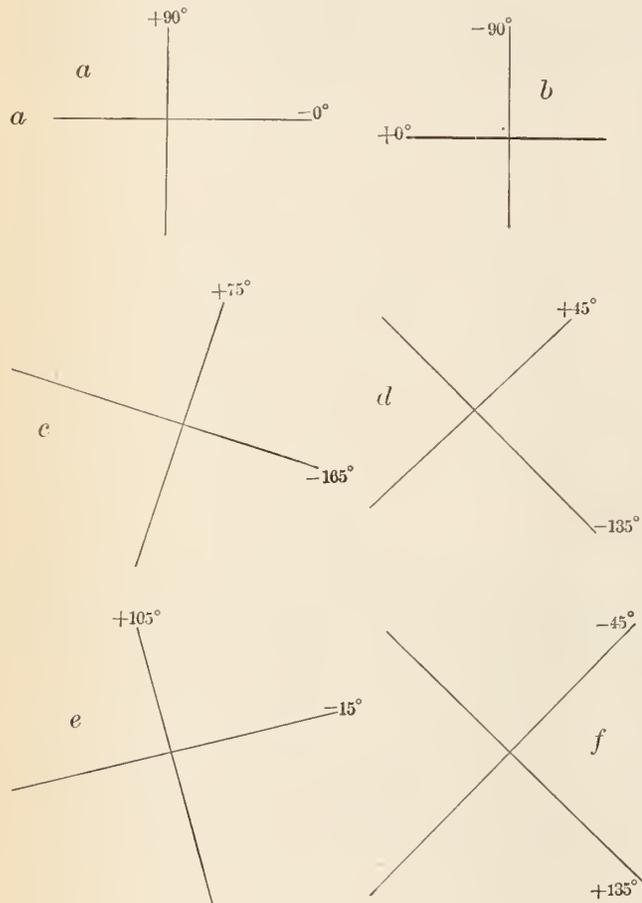

FIG. 3.

(To be concluded.)

**Infant Mortality in France.**—"At a recent meeting of the Society for the Protection of Children in France Dr. Rochard (chairman) stated that France loses every year 250,000 infants, and that out of this number there are at least 100,000 whose lives could be saved with intelligent care. These lives were the more precious in the present period, for France could no longer afford to lose them. When he stated, in 1884, that the population of France would stop increasing toward the beginning of the twentieth century, he was pooh-poohed. His prophecy has been justified sooner than he wished. The number of deaths in 1890 outnumbered the births by 38,446. It was not easy, said Dr. Rochard, to add to the births, but it was possible to diminish the death-rate among infants. The 100,000 babes that ought to be saved every year would repopulate France. He then distributed medals and prizes awarded by the society to doctors and nurses who had given their services to the society."—*British Medical Journal*.

D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JUNE 25, 1892.

THE "RAILROAD KIDNEY."

DR. CYRUS EDSON has a thoughtful paper on the hygienic relations of railway travel in the May issue of the *Dietetic Gazette*. The paper is a long one, and takes up a variety of railway situations interesting to medical men, who, as a rule, are poor travelers; it is altogether worthy of being reproduced for sale as a sanitary tract. One point—the renal consequences of an excess of railroading—interests us just now. The great evil of such excess, from the medical point of view, is not that caused by jolting, jarring, and straining the nervous apparatus, but it is dirt. The dirty condition of the cheaper trains is a manifest abomination to all tidy persons. On the better trains efforts are made to keep the travelers as free from the grimy nuisance as possible, but the dirt will force its way in. If any person who has been traveling a few hours will examine the skin of his hands, he will find it quite soiled, especially if the weather has been hot enough to cause perspiration. If, then, he will examine still more closely, he will see the fine grime in the orifices of the perspiratory ducts, in a position to sink into and close up the pores whenever the flow of perspiration ceases. How deep these little plugs or corks work their way into the integument may be inferred from the repeated washings that are necessary to thoroughly clean one's exposed surfaces after a railroad trip. This stoppage of cutaneous action throws back upon the kidneys a heavy load of impeded excretory work, and this, repeated often enough, will result in the "railroad kidney," in much the same way that serious renal disease is caused by an extensive burn on the surface of the body. The morbid consequences are alike, or parallel, chiefly for the reason that in both cases thousands, if not millions, of cutaneous outlets are completely blocked up, and renal compensation is demanded by the system.

The chief sufferers, of course, from the fouling of the skin with grime are members of that class in the community which is included under the term "railroad men"; and the cases of engineers, conductors, and brakemen are the most numerous and striking. The occasional traveler in ordinary health has not much to fear from this condition after any trip lasting a few days, but where a person is already the subject of renal disability, it is quite possible that a week or more of constant railway travel would appreciably aggravate the existing trouble. For this reason, if for no other, the commercial traveler, or "drummer," is not an infrequent sufferer from renal overwork. And it is an important item in the hygiene of this extra-hazardous vocation that habitual traveling should be given up or greatly reduced if the kidneys become impaired. This "drummer" class is largely made up of young men of good physique,

keen intelligence, and a great partiality for the external application of water. It is not to be sanguinely expected, therefore, that cases of railroad kidney will be observed frequently in the commercial traveling class. At the same time, its members may, as occasion offers, be made to understand the value of and reasons for a systematic cutaneous hygiene to persons in their way of living.

### MINOR PARAGRAPHS.

#### THE OBJECTIONS TO THE INSERTION OF DRAINAGE-TUBES INTO WOUNDS.

IN the *Maryland Medical Journal* for November 14, 1891, Professor William H. Welch summed up the objections to the insertion of drainage-tubes into wounds as follows: First, they tend to remove bacteria, which may get into a wound, from the bactericidal influence of the tissues and animal juices. Second, bacteria may travel by continuous growth or in other ways down the sides of a drainage-tube and so penetrate into a wound which they otherwise would not enter. He has repeatedly been able to demonstrate this mode of entrance of the white staphylococcus found so commonly in the epidermis. The danger of leaving any part of a drainage-tube exposed to the air is too evident to require mention. Third, the changing of dressing necessitated by the presence of drainage-tubes increases in proportion to its frequency the chances of accidental infection. Fourth, the drainage tube keeps asunder tissues which might otherwise immediately unite. Fifth, its presence as a foreign body is an irritant and increases exudation. Sixth, the withdrawal of tubes left any considerable time in wounds breaks up forming granulations and thus both prolongs the process of repair and opens the way for infection. Granulation tissue is an obstacle to the invasion of pathogenic bacteria from the surface, as has been proved by experiment. Seventh, after removal of the tube there is left a tract prone to suppurate and often slow in healing. To these Dr. Halsted adds an eighth: Tissues which have been exposed to the drainage tube are suffering from an insult which more or less impairs their vitality and hence their ability to destroy or inhibit micro-organisms.

#### THE ETIOLOGY OF SUPPURATIVE HEPATITIS.

SURGEON-CAPTAIN PATRICK HEHIR, of Hyderabad, has recently published a brochure on *The Pathological and Etiological Relations of Tropical Suppurative Hepatitis*, and concludes from his experience in India that hepatic abscess is most commonly a sequel of dysentery, arising from a secondary infective process affecting the liver through the portal circulation. Cases may arise from the action of septic organisms—such as the streptococci, staphylococci, or micrococci; or from the irritation of the products (ptomaines) of such septic organisms conveyed to the liver from the ulcerated bowels and acting primarily on the liver, which plays the part of a filter upon the blood conveyed to it by the portal vein, or from the irritation of the *Amaba coli*, or the *Cercomonas intestinalis*, or both together. Some cases may be due to malarial poisoning, the blocking up of the radicles of the portal vein by the hæmatozoa of Laveran, these organisms acting as irritants and lighting up the suppurative process. In another class of cases the abscess may be the result of acute sthenic parenchymatous inflammation resulting from climatic causes, overcrowding, alcoholic excesses, excessive heat, or chill, acting upon a liver already in a partial state of disorganization. The author makes a third class of idiopathic cases in which no assignable cause can be traced. While a known or

unknown cause may produce hepatic abscess, a statement made earlier in the paper, that micrococci are *invariably* found in pus removed by aspiration, seems to us to indicate a certain definite agent producing suppuration in a *locus minoris resistentiæ*.

#### EMIN PASHA.

THE death of Emin Pasha is announced again. This time the report seems to be credited at Berlin. The alleged cause of his death was small-pox. The real name of Emin Pasha is Edward Schnitzler, and he is in some sense the most eminent physician of his generation. He studied medicine at Breslau and Berlin, and was graduated at the latter city's university in 1864, at which time he was twenty-four years old. A strong predilection for botany and other branches of natural history, a longing for travel, and an aptitude for languages led him to go down to Constantinople in pursuit of practice, study, and adventure. His services were in almost constant requisition in semi-official positions in Turkey, Armenia, Arabia, and Syria for ten years. In 1876 he went down into Egypt, and entered the medical service of the Khedive as Dr. Emin Effendi. From that time forward his advance was rapid and picturesque, his name became a household word in three continents, and the country doctor ended by occupying the throne of a barbaric principality and introducing a semi-civilized government into the Soudan.

#### THE LATE DR. D. HAYES AGNEW.

AT the request of Mrs. Agnew, Dr. J. Howe Adams, of Philadelphia, is preparing a biography of her late distinguished husband; in consequence, he is looking for data on this subject, and is desirous of obtaining from all of Dr. Agnew's former friends, colleagues, associates, students, and acquaintances all such authentic data as relate in any way to his career or character. Dr. Agnew's acquaintance was so vast, says Dr. Adams, and his life was so actively spent among his friends, while his own modesty was so marked, that undoubtedly a great many incidents, anecdotes, characteristic stories, etc., are unknown to his family. All material, however insignificant or small, will be welcomed by Dr. Adams, and credit will be given for all such data as are used.

#### THE NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.

ON several occasions we have commended this association and the results of its work have gone on increasing in importance until now the amount paid on each death is \$1,000, being the full sum allowed by the by-laws. The present number of members is 1,106.

#### ITEMS, ETC.

**The American Chemical Society** will hold its fifth general meeting in Rochester, N. Y., on August 16th. The chairman of the committee of arrangements, Mr. A. A. Breneman, of No. 97 Water Street, New York, requests that members send him early notice of papers to be presented.

**The University of Pennsylvania.**—Under the will of the late Professor D. Hayes Agnew, the University is to possess the copyright of his surgical text-book, also many specimens and tuition-drawings, and the sum of fifty thousand dollars will go to the hospital on the death of his widow. The Maternity and Kensington Hospitals also will then be the recipients of \$1,000 each, and the College of Physicians will receive a like bequest.

**Changes of Address.**—Dr. W. Evelyn Porter, to No. 50 West Thirty-third Street; Dr. John Ridlon, from New York to No. 34 Washington Street, Chicago.

The American Gynæcological Society will hold its seventeenth annual meeting in Brooklyn on the 20th, 21st, and 22d of September.

The Honorary Degree of LL. D. has been conferred on Dr. Reynold W. Wilcox, of New York, by Maryville College, of Maryville, Tenn.

The Death of Dr. T. G. Richardson, of New Orleans, occurred in the last week in May. He was for more than thirty years a professor of surgery and other branches in Tulane University Medical School. About three years ago he retired from active college work, but remained an earnest and liberal supporter of medical educational interests in New Orleans and elsewhere. He was for twenty years dean of the Tulane Medical Faculty. He was an editor or co-editor of two or more medical journals that are now extinct. He was regarded by his older pupils as a model teacher of anatomy.

The Death of Dr. Henry F. Formad, of Philadelphia, took place on the 8th inst. He was a Russian by birth and was in his forty-sixth year. An exile for political reasons while yet a youth, he studied very diligently at Berlin and at Heidelberg.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 5 to June 18, 1892:*

DAVIS, WILLIAM B., Captain and Assistant Surgeon, is relieved from duty at Fort Clark, Texas, to take effect upon the return of Major Skinner to that post, and will report in person to the commanding officer, Fort Sam Houston, Texas, for duty.

MOSELEY, EDWARD B., Major and Surgeon, is relieved from duty at Fort Sam Houston, Texas, to take effect upon the arrival at that post of Captain Davis, and will report in person to the attending surgeon, Washington, D. C., for duty in his office.

DUNLOP, SAMUEL R., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Supply, Indian Territory, and will report in person to the commanding officer, Camp Pena Colorado, Texas, for duty at that station, relieving SKINNER, JOHN O., Major and Surgeon. Major Skinner, upon being relieved by First Lieutenant Dunlop, will rejoin his proper station, Fort Clark, Texas.

The following assignments to duty of Assistant Surgeons, recently appointed, are ordered:

McCULLOCH, CHAMPE C., JR., First Lieutenant, will proceed from Charlottesville, Va., to Fort Sam Houston, Texas, and report in person to the commanding officer of that post for duty.

REYNOLDS, FREDERICK P., First Lieutenant, will proceed from Elmira, N. Y., to Fort Monroe, Va., and report in person to the commanding officer of that post for duty.

WARE, ISAAC P., First Lieutenant, will proceed from North Anson, Me., to Fort Douglas, Utah Territory, and report in person to the commanding officer of that post for duty.

WOODSON, ROBERT S., First Lieutenant, now at Fort McPherson, Georgia, will report in person to the commanding officer of that post for duty.

BREWER, MADISON M., First Lieutenant, is relieved from temporary duty in the Surgeon-General's Office, Washington, D. C., and will proceed to David's Island, N. Y., and report in person to the commanding officer of that post for duty.

DESHON, GEORGE D., First Lieutenant, now at Columbus Barracks, Ohio, will report in person to the commanding officer of that post for duty.

IEGER, ANTHONY, Colonel and Surgeon, is granted leave of absence for four months, to take effect after June 30, 1892.

GORGAS, WILLIAM C., Captain and Assistant Surgeon. The leave of absence granted is extended one month.

HARRIS, HENRY S. T., Captain and Assistant Surgeon. The leave of absence granted for seven days is extended twenty-three days.

IRELAND, MERRITTE W., First Lieutenant and Assistant Surgeon, is relieved from temporary duty at Fort Yates, N. D., and will rejoin his proper station, Fort Riley, Kansas.

FISHER, HENRY C., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer, Fort Yates, N. D., for duty at that station.

#### Appointment.

To be Chief of the Record and Pension Office of the War Department, with the rank of Colonel, in accordance with the act of May 9, 1892:

AINSWORTH, FRED C., Major and Surgeon, May 27, 1892, to fill an original vacancy.

#### Commission vacated by New Appointment.

AINSWORTH, FRED C., Colonel and Chief of the Record and Pension Office. His commission as Surgeon, with the rank of Major, June 1, 1892.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending June 18, 1892:*

STITT, E. R., Assistant Surgeon. Detached from the Naval Hospital, Philadelphia, and ordered to examination for promotion, and then to Bureau of Medicine and Surgery.

BAILEY, T. B., Assistant Surgeon. Detached from the Receiving-ship Minnesota, and ordered to examination for promotion, and then to Hospital, Philadelphia, Pa.

BYRNES, J. C., Passed Assistant Surgeon. Ordered to special duty at Norfolk and Portsmouth, Va.

WILSON, H. D., Assistant Surgeon. Ordered to the Receiving-ship Minnesota.

WILSON, G. B., Passed Assistant Surgeon. Ordered to temporary duty at the Naval Hospital, Chelsea, Mass.

ARNOLD, W. F., Passed Assistant Surgeon. Detached from U. S. Training-ship Richmond, and placed on waiting orders.

BARNUM, M. W., Assistant Surgeon. Detached from Naval Hospital, Washington, D. C., and ordered to the U. S. Training-ship Richmond.

PERCY, H. T., Passed Assistant Surgeon. Ordered to the Naval Hospital, Washington, D. C.

PICKRELL, GEORGE M. C., Passed Assistant Surgeon. Detached from the Naval Hospital, Norfolk, Virginia, and ordered to the U. S. Steamer Newark.

#### Society Meetings for the Coming Week:

MONDAY, June 27th: Medical Society of the County of New York; Boston Society for Medical Improvement; Cambridge, Mass., Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, June 28th: Medical Society of New Jersey (first day—Atlantic City); Buffalo Obstetrical Society.

WEDNESDAY, June 29th: Medical Society of New Jersey (second day); Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield).

## Letters to the Editor.

### BANDAGE-CUTTING.

DECATUR, ILL., May 7, 1892.

To the Editor of the New York Medical Journal:

SIR: In the *Journal* of March 26th is a short article by Dr. Southgate Leigh, describing a number of new and improved instruments. The last thing described is a bandage-cutter, and I infer that he, like the majority of practitioners, finds the ready-rolled bandages of the shops too expensive. I think I have hit on a scheme for bandage-cutting that will be of great practical utility to the surgeon who desires to roll his own bandages. I purchase a bolt (or less quantity) of muslin and take it to a printing-office where they have a paper-cutter, and in five minutes the entire bolt can be cut into bandages of different widths, and afterward rolled in lengths to suit. This gives a nice even bandage, and is in every way superior to those torn or cut with scissors.

M. H. FARMER, M. D.

## Proceedings of Societies.

### AMERICAN MEDICAL ASSOCIATION.

*Forty-third Annual Meeting, held in Detroit on Tuesday, Wednesday, Thursday, and Friday, June 7, 8, 9, and 10, 1892.*

The President, Dr. HENRY O. MAROX, of Boston, in the Chair.

(Concluded from page 694.)

**Proposed Amendments to the Constitution.**—An amendment was proposed by Dr. C. A. L. REED, of Ohio, providing that the association admit to membership physicians from the Dominion of Canada, Newfoundland, and Labrador. The matter was to be referred to a committee of the association, which should confer with proper committees from the countries mentioned.

The PRESIDENT appointed as the committee for the association Dr. C. A. L. Reed, Dr. N. S. Davis, Dr. H. O. Walker, Dr. C. A. Lindsley, and Dr. C. G. Conn. The constitution required that such an amendment should lie over for a year before adoption.

An amendment to the constitution was also offered that no physician should be admitted to membership in the association who had not been four years in practice. Action on this was also deferred for a year.

A recommendation was received from the Section in Physiology and Dietetics that the Haddock Pure Food Bill, now before Congress, be endorsed, but, as the exact terms of the bill were not known to the meeting, the recommendation was tabled.

The Committee on Incorporation recommended that incorporation be deferred for the present, as the association might thereby be more or less involved in litigation.

Dr. QUMBY, of New Jersey, offered as an amendment to the constitution that Thursday of each annual meeting be devoted exclusively to section work. This was tabled.

A committee was appointed by the president to audit the report of the treasurer of the Rush Monument Fund.

The committee on the matter of railroad surgeons reported that two complaints were before it. One was that railroad surgeons were supposed to care for injured passengers and employees without due regard to their ethical relations to other professional brethren; the other, that they took inadequate compensation for their work, and so tended to lower the standard and dignity of the profession. The committee denounced the custom of underbidding in order to get practice, and discussed at length the contract system as applicable to surgeons. It was thought that this system was too extensive and involved too large a portion of the medical profession who were under contract, wholly or in part, to be crushed by adverse resolutions or criticism. The contract system, on the whole, was not to be encouraged. The report was adopted.

**Officers for the Ensuing Year.**—The Committee on Nominations reported as follows: For president, Dr. Hunter McGuire, of Virginia; for vice-president, Dr. H. O. Walker, of Michigan; for treasurer, Dr. R. J. Dunglison, of Pennsylvania; and for secretary, Dr. W. B. Atkinson, of Pennsylvania. It recommended that the next meeting be held at Milwaukee, and also that the code of ethics of the association be made broader.

**The Address on State Medicine** was delivered by Dr. J. BERLIAN LINDSLEY, of Tennessee. His attention had first been called to the importance of his subject by reading, while a

medical student, in 1843, a book entitled *An Inquiry into the Sanitary Condition of the Laboring Population of Great Britain*, and this had influenced the thoughts, studies, and pursuits of his life as few other books had done. The influence of the book in Great Britain had been enormous. Since the time that it was written the great feature of British history had been the constant, steady elevation of the masses, and the leading topic under that head had been the public health. In 1853 the city of New Orleans was ravaged by yellow fever, which called forth the report by Dr. E. H. Barton upon the sanitary condition of New Orleans, and also a voluminous report by the New Orleans Board of Health. If the teachings of these volumes had been sufficiently followed, the conditions, commercial as well as physical, of that city would have greatly improved. Another notable report in the literature of state medicine was that which was issued in 1865, entitled *Report of the Council of Hygiene and Public Health of the Citizens' Association of New York upon the Sanitary Condition of the City*. Sanitary reform in Massachusetts was much influenced by Shattuck's report in 1850 on the sanitary condition of Massachusetts. The first State board of health was established in that State.

Sanitary reform, then, was inaugurated not so much by the medical profession as by the general public, looking at first to its protection from disastrous epidemics, and next to relief from preventable diseases and improvement in daily health.

Medical men were naturally called to assist in a reform of this character, and they soon assumed a leading part. But their influence should not be predominant, for it was law and not medicine that was chiefly concerned. Medical science could dictate the kind of laws that should be made for the promotion of the public health, but it was powerless to enforce those laws. A powerful auxiliary to sanitary science was found in the articles upon public and private hygiene which were constantly appearing in the periodical literature. The advances which had been made in chemistry, physics, and biology had been notably useful in that direction. Though the governments of most civilized nations realized the vital importance of sanitary science, and fostered or controlled institutions for its furtherance, the American Government was most backward in this particular. Here, then, was a fine opportunity for completion by the general Government of the work which had been so admirably developed by local and State boards of health. This was especially indicated, in view of the great extent of our country, with its varieties of climate and disease. The untimely end of the National Board of Health, which was established in 1879 and expired after a few years of existence, was much to be regretted, notwithstanding the fact that its decline was concurrent with a noteworthy expansion of the Marine-Hospital Service, which in some respects represented the Government in the field of preventive medicine. The evolution of governmental supervision of the public health would not be complete until a Department of Public Health was established, suitable dignity being conferred upon its presiding officer. This would necessarily include the vast interests of the Marine-Hospital Service; a great bureau of vital statistics, which would supersede the Census Office and be in operation continually; a bureau for the minute topographical survey of the entire country, with the mapping of its results on an extensive scale; and possibly other departments which were now under the control of other branches of the Government.

The Museum of Hygiene, now under the control of the Navy Department, and the Library of the Surgeon-General's Office were illustrious examples of what the Government could do in the way of State medicine, for, if a separate bureau for this subject were established, these two institutions would necessarily be incorporated in it.

Until recent years the American Medical Association had been too indifferent to the part that should be played by the Government in caring for the public health, but, happily, that had been changed; the addresses in state medicine from year to year had been stimulating to the work, and the same was true of the addresses from the presidential chair. It was recommended that a committee of the association be appointed to co-operate with other national organizations in which state medicine was a matter of investigation, including the American Public Health Association, the American Association for the Advancement of Science, and the Congress of Physicians and Surgeons.

The PRESIDENT suggested that before the adjournment some expression of appreciation of the courtesies and hospitalities which the association had received should be made. Dr. N. S. Davis, of Illinois, and Dr. H. D. Didama, of New York State, responded to this suggestion in complimentary remarks, and resolutions expressing gratitude and appreciation were also offered by a committee appointed for the purpose, and adopted.

The president for the ensuing year, Dr. Hunter McGuire, was then introduced, and the meeting was adjourned.

#### NEW YORK SURGICAL SOCIETY.

*Meeting of February 10, 1892.*

The President, Dr. ARPAD G. GERSTER, in the Chair.

#### Compression Myelitis in Connection with Pott's Disease.

—Dr. V. P. GIBNEY read a paper on this subject and referred to a previous paper read in 1879, in which he had reported the histories of fifty-eight cases. Those cases he had carefully followed up, and, so far as he had been able to ascertain, they had shown a mortality of 10.5 per cent. from the disease. With many of them the paralysis or paraplegia had lasted from four to ten years, and then recovery had taken place.

The author's present table included a series of thirty-two cases in which the paralysis had continued from two months to two years and ten months, the average being eight months. He described the method by which these cases were usually treated, which consisted in the free administration of iodide of potassium and Fleming's method of extension. Several typical cases from his table were narrated. Frequently as much as one hundred grains of iodide of potassium, in solution, were given to children not more than eight years of age. The progress of patients who were cared for at home was frequently interfered with by the carelessness of parents in attending to their dressings and their failure to bring them sufficiently often to the physician for inspection. The supporting apparatus which was applied in these cases should be immovable and should be worn for a long time. Relapses frequently occurred in consequence of changes made in the apparatus. By some surgeons a hopeless view was taken of such cases. It must be admitted that the prognosis was difficult. The hopeless cases were those in which the disease involved the ganglion cells of the spinal cord, distortions and deformities of the limbs resulting.

Dr. ROBERT ABBE thought that operations in cases of the disease under discussion were simple and apt to be successful. There was no great risk to the patient in the operation, which he believed was called for only in very bad cases. He had operated in two cases successfully.

Dr. J. D. BRYANT had seen no occasion for operation in the cases which had come under his notice. The patients he had seen had recovered without operation, and he thought that interference by operation sometimes made matters worse.

Dr. GEORGE R. FOWLER's experience with operative proced-

ures had been unsatisfactory. He had operated in two cases, both of which had resulted fatally.

Dr. CHARLES MCBURNEY had not operated for this disease. He was in favor of conservative methods of treatment during the early stages, while those cases which were far advanced or had come to a standstill might be suitable for operation. The indications for operation were similar to those that obtained in cases of fracture of the spine, in which, partial repair having taken place, and so some support having been supplied, operations were better borne and more successful. One should generally try the effect of supporting apparatus first.

The PRESIDENT had operated successfully in two very bad cases in which the symptoms of compression had increased in urgency very rapidly. In both of them the compression symptoms had been due to a subdural effusion of pus, and when this was removed the paralysis disappeared rapidly.

Dr. GIBNEY had found that the opinions of neurologists in regard to the propriety of operating differed decidedly. It was difficult to determine this point by electrical tests.

**Thiersch's Method of Skin-grafting.**—Dr. MCBURNEY presented two cases in which ulcers of the leg had been treated by Thiersch's method of skin-grafting. In the first case there had been a large ulcer of the heel and of the inner aspect of the ankle, which had followed a severe injury and had existed for thirty-two years. The tissues of the ulcer had been excised and four grafts from the thigh applied. All of these had united and the result had been complete healing. In the second case there had been large ulcers upon the anterior aspect of both legs. In this case also complete healing had been obtained at once. In performing the operation the wound was frequently irrigated with a salt solution, rubber tissue, moistened with the same solution, was applied, and over this were placed compresses, also moistened, the salt solution being renewed upon the compresses at proper intervals. Both syphilitic and tuberculous ulcers had been operated upon by this method with good results.

#### A Neglected Method of modifying General Anæsthesia.

—Dr. MCBURNEY read a paper thus entitled. The question had frequently occurred to him whether we did not anæsthetize too extensively in operative procedures. While it was desirable to anæsthetize only the nerve centers, by the methods which were in common use, the brain, the nerve centers, the blood, and all the tissues were saturated with the anæsthetic, and all the agencies of elimination were taxed to the utmost in trying to dispose of it. It therefore seemed to him desirable to exclude as large a portion of the circulating fluid as possible from the action of the anæsthetic, and this was done by confining blood in the limbs by bands securely fastened around them. This method was not a new one, but had been used in previous years by Corning, Sweatnam and Aiken, of Toronto, and A. C. Post. Corning had advised compression of the limbs with sufficient firmness to exclude all communication of the circulating fluid in them from the trunk and head. The author had practiced this method in ten cases, including a variety of operations. An ordinary ether cone had been used, with from an ounce to three ounces of ether. There was usually no struggling, quiet anæsthesia resulted in from two to five minutes, and there was no congestion of the face. There was very little vomiting or discharge of mucus or saliva. When the operation was completed the limbs were raised, the bandages were removed, and consciousness quickly returned. There might be dangers in the method, but they were not as yet apparent. It was thought that the method might obviate shock to a certain extent, also disturbance of the kidneys and bronchitis. The method was then practically demonstrated upon a man, about twenty years of age, in apparently good physical condition. There was very little struggling. Three ounces of ether were used and com-

plete anaesthesia was induced in from eight to nine minutes. The bandages were then removed and consciousness returned in two minutes. The subject answered questions intelligently, and was able to get off the table and put on his clothes.

Dr. ABBE had observed that the patient's breathing had been somewhat shallow during the anaesthesia, and diaphragmatic in character. He was surprised at the rapidity with which consciousness returned, and also that the face did not become either pallid or blue, but of a natural red.

Dr. BRYANT was much pleased with the demonstration, and believed the method worthy of further investigation.

Dr. J. D. RUSHMORE could not accept the statement that pure blood was thrown into the circulation as the bandages were removed. Having been confined in the tissues, it was quite impure, but it was quickly oxygenated as it passed into the lungs and was certainly not saturated with the anaesthetic. He did not think it desirable to anaesthetize a patient with great rapidity.

Dr. McBURNEY thought it important that the constriction should be sufficient, not only to prevent the return of venous blood, but also to shut off the supply from the arteries. Of course the method should not be used upon persons with diseased arteries, and if the compressing bands were too narrow injury might be done to the nerves. The brain and trunk were to a certain extent anaemic during anaesthesia by this method, and this might have a bearing upon the operation to be performed. The shallow breathing might be due to the possible anaemia of the lungs. There was a possibility that haemorrhage might occur in the wound after the circulation was restored; hence it was well to defer putting in the final stitches until safety from this accident was assured. If morphine was injected hypodermically between the bandages and the heart the quantity should be much smaller than if it was allowed to permeate the entire circulation.

#### *Meeting of February 24, 1892.*

The President, Dr. ARPAD G. GERSTER, in the Chair.

**Deformity of the Lower Extremity following Excision of the Hip Joint.**—Dr. V. P. GIBNEY presented a patient in whom disease of the right ankle joint had commenced in his fourteenth month. The affected bone was excised by Dr. Lange. Three months later hip trouble had commenced and the head of the femur had been excised at the German Hospital. Sinuses had resulted that had been scraped several times since, and at present there was one over the great trochanter. The foot was now in the position of equino-varus. The thigh could be flexed to 90°, but there was limited motion of the limb with atrophy. The femur, tibia, and fibula were of two thirds of the length of those bones on the unaffected side.

The speaker presented a second case, that of a patient aged eight years and a half, in whom the head of the femur had been excised by a surgeon in one of the general hospitals, and at present extension could be made to about 155°. There was limited adduction, also decided shortening. The question in such cases was whether it was better to open the old wound, scrape out the diseased bone, and divide the femur, or to continue temporizing; and in the first case presented was it better to correct the ankle deformity or amputate the foot?

Dr. F. LANGE stated that he had operated on the ankle of the first patient shown when the boy was three years old, and Dr. W. Meyer, in later years, had operated upon the same child for tubercular disease of the hip joint. The future treatment would depend upon the possibility of healing the sinuses. Amputation might be performed below the knee joint and an artificial leg employed.

Dr. J. A. WYETH believed it would be better to apply in that case some apparatus that would fit on the foot, rather than use prothetic apparatus after amputation.

Dr. GIBNEY stated that he thought in his first case he would attempt to heal the sinus by an operation, divide the femur subcutaneously, keep the foot in a plaster-of-Paris dressing, and then apply such an apparatus as Dr. Wyeth had referred to. In the second case he proposed doing a subcutaneous osteotomy.

**Intestinal Obstruction.**—Dr. FRANK HARTLEY presented a patient on whom an operation had been performed two years ago for suppurative appendicitis with acute suppurative peritonitis. In November, 1891, he presented symptoms of intestinal obstruction. An incision was made in the median line and a slender constricting band was found and removed. It was the second case of the kind that he had operated on.

Dr. L. A. STIMSON thought that such cases as this exhibited the ultimate, as well as the immediate, risks attending late operations for appendicitis, an operation that could be considered neither simple nor safe.

Dr. R. H. M. DAWBARN wished to call attention to a point that he believed to be new in reference to laparotomy for appendicitis, and that was, the way in which to find the appendix. Where agglutination had not occurred, the small intestines were continually falling into the field of operation and annoying the surgeon. In a dozen instances he had found it a simple expedient to change the patient from his back to the left side and to pull the abdomen forward (away from the spine), thus forming a space into which the small intestines would fall, the caecum being, however, held in position by its short mesentery.

**Pyloroplasty for Stenosis after the Heineke-Mikulicz Method.**—Dr. LANGE presented a man, twenty-nine years old, whose family history was good. He had been in good health until about six years ago, when he commenced to suffer from dyspeptic trouble. He was treated for a long time for nervous dyspepsia and gastric catarrh, but never for supposed ulcer of the stomach. Though he often vomited, he never vomited blood, and no blood was observed in his stools except what was readily explained by the presence of moderate piles. Within the last year he had often vomited large masses containing particles of food that had been swallowed from a day to three days previously. The degree of acidity had often been examined and found to be abnormally great, as stated by Dr. Alfred Meyer, his attending physician. He had often very severe cramp-like pain in the region of the stomach, radiating toward the back and the space between the shoulders. His bowels were regular.

The speaker saw the patient, in consultation with Dr. Alfred Meyer, on January 4th. An examination by inflation proved the stomach to be considerably dilated. An indistinct hardness could be felt in the region of the pylorus, also some pain on deep pressure. The patient was emaciated but did not present a cachectic appearance. On the 8th of January laparotomy was done. The pylorus was covered by the gall-bladder, omentum, and large intestine, which had to be separated with the thermo-cantery, scissors, and blunt manipulations to get access to the pylorus. The separation of the gall-bladder was especially tedious, and in this attempt the lumen of the stomach, close to the stricture, was burned into. The pylorus was greatly narrowed and felt like a hard ring; a longitudinal incision an inch long into the stomach and a like incision into the duodenum proved its lumen as narrow as a lead-pencil. The longitudinal wound was closed by two rows of suture, an internal catgut and an external silk suture. The application of a loose iodoform-gauze tampon and union of the laparotomy wound finished the operation. The wound through the abdominal wall was a

longitudinal incision in the linea alba, with a shorter transverse one to the right, about three or four inches in length. The operation was very tedious, requiring over two hours. The patient made an uninterrupted recovery and was discharged after four weeks. His pain had not returned since the date of the operation, and he was in fair health and gaining.

From a paper by Dr. Senn, who reported two of his cases with favorable result in November, 1891, it appeared that this was the eleventh case on record, and that the operation yielded safe and good results. The speaker desired to state that Dr. Prudden's examination of a specimen from the case of gastric ulcer presented at a December meeting had shown it to be carcinomatous.

Dr. WYETH asked whether he considered this operation preferable.

Dr. LANGE replied that he thought the functional results were better in Mikuliez's.

**Musculo-spiral Paralysis complicating Fracture of the Humerus.**—Dr. F. W. MURRAY read a paper having this title. (See page 708.)

Dr. WYETH said that in a case of fracture of the humerus symptoms of musculo-spiral paralysis appeared, and two weeks after the injury he operated and successfully released the nerve. An analogous condition was sometimes caused by the plaster dressing on a fractured patella compressing the external popliteal nerve and producing talipes.

Dr. STIMSON said that in one of his own cases, referred to by Dr. Murray, there was no apparent injury to the nerve, and in another there was a bony canal within which the nerve was noticeably smaller, but not tightly held; whether the nerve was ever actually compressed in the canal needed demonstration. In one case that he had seen, the nerve was injured by the violent grasping of an assistant in turning the humerus so that the end of the bone could be excised; this patient recovered spontaneously in two years. It seemed to him that the interference with the function of this nerve was not always the result of compression, but rather of some unknown factor; this, however, need not interfere with the advisability of operating. He would always seek for the nerve below the point where it was hidden by cicatricial tissue, and then follow it up.

Dr. ROBERT ABBE had had no experience in musculo-spiral paralysis, but the demand for surgical interference should be heeded in any case where the nerve was probably stretched across a sharp edge of bone. He recalled a case in which the popliteal nerve had been stretched across the sharp fractured end of the femur at the epiphysis that resulted in fatal tetanus in spite of amputation.

Dr. J. D. BRYANT recalled a case of musculo-spiral paralysis in which the question of a suit for damages arose, the parents alleging malpractice because paretic symptoms developed after the injury. It would be wise for the surgeon, in treating fracture of the humerus, to test the muscles supplied by this nerve at the time of the injury and frequently afterward, so "as to cast an anchor to the windward," in case of subsequent legal complications.

Dr. HARTLEY reported a case of paralysis of the posterior interosseous branch of the musculo-spiral nerve in a case of fracture through the internal condyle of the humerus above the capitellum. At the operation he found the bend of the nerve caught between the ends of the fractured bone; he released the nerve and approximated the fracture, and there was complete recovery. In this case, as in two others published in the *Roosevelt Hospital Reports*, this branch was given off rather higher than usual.

**Intestinal Strangulation by a Fibrous Band.**—Dr. BRYANT presented a specimen that he had removed from a musician,

aged sixty-six years, who had never suffered from any intestinal or abdominal trouble until forty-eight hours before the speaker was called in. He had excruciating pain, and was almost pulseless when seen, the abdomen was distended, and intestinal strangulation was obvious. Despite the grave condition, the abdomen was opened, and a considerable portion of gangrenous jejunum (fifteen inches) was exposed. This was drawn out until a fibrous band, connected with an intestinal diverticulum, was found constricting it. He removed the band, opened and cleaned the intestine, and cleansed the abdominal cavity. The patient lived fourteen hours.

Dr. DAWBARN asked whether this was an example of Meckel's diverticulum.

Dr. BRYANT stated that it was connected with the jejunum, but he could not examine it as he would have desired owing to inability to obtain a post-mortem; therefore he could not reply definitely.

## NEW YORK ACADEMY OF MEDICINE.

SECTION IN ORTHOPÆDIC SURGERY.

*Meeting of May 20, 1892.*

Dr. HENRY LING-TAYLOR, Chairman.

**Congenital Dislocation of Both Patellæ.**—Dr. S. KETCH presented a little girl who at first glance seemed to have only knock-knee, but on flexing the limbs, a complete dislocation of the patella downward and forward was observed, and the dislocation could be readily reduced by extending the limb. The deformity was much more marked on the right side. The condition was probably congenital, although it had not been noticed by the mother until recently, as the child was able to walk with no more difficulty than was observed in an ordinary case of knock-knee. Dr. Shaffer had suggested that this was the opposite of the condition which he had described under the head of elongation of the ligamentum patellæ at the last meeting of the American Orthopædic Association.

Dr. JOHN RIDLON said that he had seen three such cases in the practice of the late Mr. Thomas. The treatment had consisted in hammering the deficient condyle with an egg-shaped wooden mallet, and in two of the cases the treatment had already effected sufficient development to prevent dislocation, and in the other case the treatment had only just been begun.

Dr. W. R. TOWNSEND said that he had presented some time ago to the Surgical Section of the Academy of Medicine a colored girl who could, by muscular action, produce at will a complete dislocation of both patellæ, either to the outer or to the inner side. A knee-cap was applied, and an effort made to restrict the movements of the fibers of the vastus externus and internus, which seemed to be abnormally developed. She was kept under observation for six or eight months, and at the end of this time she could not produce the dislocation at will, and the dislocation occurred quite infrequently.

Dr. N. M. SHAFFER said that in his case of elongated ligamentum patellæ the man had had a fall which was followed by an outward dislocation of the patella on the right side. After consultation with several other surgeons, in view of the fact that the intercondyloid notch was filled by an exostosis, it was considered best to make no attempt at reduction, and at present, although the patella lay on the outer aspect of the joint, the man was perfectly able to walk ten or fifteen miles a day. In the case just presented, he did not think the external condyle was deficient, but the ligamentum patellæ was so short that the patella, instead of passing over the trochlea, was drawn down to a point where, owing to the knock-knee, it was very easily dislocated. On this account, he thought that treatment directed toward securing an elongation of the ligament would

be more apt to prove successful than simply hammering the outer condyle.

Dr. KETCH agreed with the last speaker as to the inadvisability of resorting to operative measures. Not long ago he had seen a young lady with a somewhat similar condition. Twelve years before, the patella had been dislocated by muscular action, and this had again occurred shortly before he saw her. Reduction was easily effected by extending the limb.

**Ankylosis of the Hip.**—Dr. IRVING S. HAYNES, present by invitation, exhibited a specimen of this condition which he had found in the dissecting room of the University Medical College. The subject was a man about twenty-five or thirty years of age. The limb was slightly flexed, adducted, and rotated inward. A sinus opened about half an inch below Ponpart's ligament and an inch internal to the anterior superior spinous process. It passed backward and soon divided into two tracts, one leading down to the front of the great trochanter, the other up under Ponpart's ligament into the iliacus, and then into the obturator internus muscle, then around the middle of the outer border of the obturator foramen into the cotyloid notch, and so into the hip joint. The iliacus and obturator muscles, as well as all the muscles acting upon the hip joint, had undergone extensive absorption and fibrous degeneration. The center of the disease, and the starting point, seemed to have been in the head of the femur, but there was also a focus in the epiphyseal line of the great trochanter, which communicated with that found in the head of the femur by a sinus running through the neck and also opened in front through one or two small openings. Another sinus seemed to have led from the acetabulum through the cancellous portion of the ilium into the iliac fossa, where the opening was surrounded by bony formations. Between the ilium and the sacrum there was slight mobility of a gliding nature, which the speaker had never observed before and which was probably intended to partially compensate for the lack of motion at the hip. There was no evidence of the disease in the capsule of the joint. The abscess cavities were limited to the absorbed portions of the iliacus and obturator internus muscles.

**Arthritis Deformans.**—Dr. HAYNES also exhibited a specimen of this condition showing erosion and reproduction of bone, with a depression in the acetabulum and disappearance of the ligamentum teres. The motions of the joint were slightly limited in every direction. The specimen had been removed from an old subject.

**The Treatment of Large Abscesses in Pott's Disease.**—Dr. W. O. PLIMPTON presented several cases of Pott's disease with large abscesses as an illustration of the treatment which he advocated. He did not favor aspiration, because he thought that after this had been done the abscesses were likely to continue to enlarge and burrow into the tissues. While admitting that abscesses were not infrequently absorbed, he wished to deprecate the let-alone treatment of large abscesses which tended to burrow deeply into the tissues, threatening to inoculate these tissues and often causing mechanical deformities of other parts.

Dr. TOWNSEND said that the location of the tube in the first case reminded him of an accident which had occurred about a year before. He was hastily summoned to the hospital on account of one of the patients having a hæmorrhage. He found that a patient with a large psoas abscess which had been opened and a drainage-tube inserted three weeks before, had suddenly begun to bleed profusely. The hæmorrhage was arterial, and, with the assistance of Dr. W. T. Bull, he cut down and found that the pressure of the drainage-tube had caused a large perforation in the femoral artery. He accordingly tied the artery above and below the perforation, and the child recovered without further accident.

Dr. KETCH thought the cases presented very much the appearance of those which he had seen in the hospital when it was the rule to open all abscesses as soon as they approached the surface. They did not seem to him to differ materially in their course from those where the abscesses were allowed to open spontaneously, and he could not see that anything had been gained by this method of treatment.

Dr. RIDLON asked if the drainage-tube had been left in for so long a time for fear that the opening would close up, and make another operation necessary. He had always thought that it was not requisite to leave the tube in more than a few days.

Dr. A. M. PHELPS thought that the second patient had had a decided advantage over the first in being subjected to the operation at a much earlier stage. The slightest increase in an abscess, in his opinion, warranted prompt incision. He spoke emphatically because the Section had almost been committed to the idea that it was better for these abscesses to take care of themselves. But it must not be forgotten that they were originally collections of tuberculous material, and that when they became infected with pyogenic germs, as almost inevitably occurred, there would be a rapid burrowing of the pus. Another reason for opening them was that they exerted an injurious effect by the internal pressure of the exudate upon the carious foci in the diseased vertebræ, keeping them bathed constantly and furnishing a fertile source of the subsequent breaking down of these vertebræ and of a consequent increase in the deformity.

Dr. KETCH thought that the previous speaker had not correctly stated the position of the Section on this subject. He thought it would be more correct to say that they took the ground that so many of these abscesses disappeared spontaneously under proper mechanical treatment that something more than mere accident was necessary to explain it, and that these collections of pus caused injurious pressure had not been proved. The proof of this would be found in a marked increase in the size of the deformity, but in disease of the dorso-lumbar spine, where these abscesses were the most frequent, this did not occur, and Dr. Myers had recently presented a boy who had had two large iliac abscesses disappear spontaneously, and yet there had been no increase in the kyphosis, as shown by repeated and careful tracings.

Dr. SHAFER said that extensive observation had taught him that, with efficient mechanical treatment, the abscesses of Pott's disease almost uniformly pursued a benign course, and he believed that the time would come when those who now operated would see their error. He had seen in the practice of some of the best surgeons in New York deaths occur after operating upon just such abscesses. When an abscess was very tense, and there were severe local or constitutional symptoms, everybody recognized the propriety of incision, but ordinarily these abscesses were flaccid and did not cause any such "daunting up" and injurious pressure as had been described by Dr. Phelps.

Dr. WHITMAN could see no good reason for waiting until the abscesses appeared below Ponpart's ligament. When first discovered they should be aspirated, and, if this failed, iodiform emulsion should be injected. Surely a method of treating the abscesses of Pott's disease which yielded in the hands of Brunz fifty successful cases out of fifty-two, and in those of Fraenkel eighteen out of twenty, was one which deserved a fair trial before resorting to severer measures. If aspiration and the injection of iodiform emulsion proved unsuccessful, the method of evacuation recommended by Barker and Treves, with immediate closure of the wound, might be employed before resorting to open drainage.

Dr. PLIMPTON said that the tube had been left in for free drainage, as it had been found that where it was removed shortly after operation the exuberant granulations choked up the sinus and gave rise to a great deal more trouble and discomfort than where the tube was retained. At the time of the operation he had had in mind the possibility of accident from having the tube in too close proximity to the femoral artery, and in this particular case there were dense cicatricial barriers between the tube and the artery. Small and not readily accessible abscesses should not be interfered with unless they caused some disturbance, but he would not hesitate, if circumstances seemed to demand it, to open them above Poupart's ligament. The existence of pressure within an abscess and its effect upon the general health were well demonstrated in one case in which he removed about half a pint of the contents of the abscess by aspiration, with the result of causing an immediate return of the child's appetite and a prompt relief from pain. He had seen the iodoform emulsion used in a number of instances without apparent benefit. In considering the percentage of abscesses which disappeared spontaneously, it must be remembered that many of them were small abscesses or were nothing but fluid in the joint, so that the statistics on this point were very defective.

**A Contribution to the Study of Non-deforming Club-foot.**—Dr. L. W. HUBBARD read a paper with this title.

**A New Apparatus for overcoming Abduction of the Thigh in Hip-joint Disease.**—Dr. SHAFFER exhibited a new apparatus which he had devised for the purpose of overcoming the abduction of the thigh in hip-joint disease, and at the same time avoiding the infliction of any traumatism upon the joint. It consisted of a thoracic attachment to the ordinary long hip splint, with an arrangement of curved levers actuated by a key, by which motion was imparted to the limb in a direction downward and inward, instead of, as in other instruments of this class, inward and upward. This was the chief feature, and it was on this account that traumatism was avoided. It could be attached to any ordinary long traction splint, and, like the thoracic part, it was to be used only as a temporary arrangement for reducing the deformity.

Dr. PUELP said that he was glad to see that Dr. Shaffer had come to recognize the fact that we could not act upon the hip joint with any degree of precision without taking hold of the thorax; but he failed to see any necessity for such an apparatus as the one shown, because his lateral traction splint did the same thing, and no patient with hip-joint disease need recover with angular deformity. Since he had devised and made use of his lateral traction fixation splint, which acted on the same principle as the apparatus just exhibited, he had not seen a case of angular deformity. If such a thoracic splint was applied after the deformity had once been overcome, recovery must take place without angular deformity.

Dr. SHAFFER explained that the apparatus he had just presented was intended only as a temporary apparatus for overcoming persistent abduction of the thigh, and he considered it a very serious mistake to use the thoracic attachment in the ordinary treatment of hip-joint disease, because it limited the motion of the spinal column, and this would necessarily increase the strain upon the diseased joint. It was for this reason that he had discarded the thoracic addition to the hip splint many years ago. The idea of his new apparatus was to provide a temporary means of overcoming abduction, and it was only to be worn long enough to accomplish this purpose, and then it was so arranged that the abduction and thoracic portions could be removed readily, leaving the ordinary hip splint, which permitted a free movement of the dorso-lumbar spine, and thus diminished the traumatism at the hip, which was best

shown when a patient with hip-joint disease and dorso-lumbar caries attempted locomotion.

## Book Notices.

*The Diseases of the Mouth in Children* (Non-surgical). By F. FORCHHEIMER, M. D., Professor of Physiology and Clinical Diseases of Children, Medical College of Ohio, etc. Philadelphia: J. B. Lippincott Company, 1892.

THE contents of this volume were first published in the form of a series of articles in the *Archives of Pediatrics*. Many of the articles have, however, been revised and added to.

One of the principal motives of their republication was to furnish the medical student with a systematic course which should give him a working basis for his usefulness as a practitioner. The author has endeavored to bring together the facts in connection with the non-surgical diseases of the mouth in children—something which has never been done before in the English language.

The older physicians were very careful about the examination of the mouth, especially the tongue, but in these days the examination is usually performed in rather a perfunctory manner. The diagnostic value of certain changes is largely disputed, and probably justly so. At the same time it is certain, as the author says, that the older physicians, with their limited means, made diagnoses that were very wonderful; and it is equally certain that we, with all our appliances, overlook very important conditions.

There are chapters on the various forms of stomatitis, each variety being thoroughly discussed as regards its ætiology, pathology, diagnosis, prognosis, and treatment. The phenomena of dentition are also considered in a separate chapter. The author takes strong ground against lancing the gums, believing it to be useless either as giving relief to symptoms, or as facilitating or hastening teething.

The book is well printed, the style is clear and forcible, and the views expressed are evidently based upon wide reading as well as a full personal experience.

*A Treatise on Practical Anatomy* for Students of Anatomy and Surgery. By HENRY C. BOENNING, M. D., Lecturer on Anatomy and Surgery in the Philadelphia School of Anatomy, etc. Philadelphia and London: F. A. Davis, 1891.

THE author has endeavored to arrange the subject-matter in this book so as to make it equally serviceable as a text-book on anatomy and as a guide in dissection.

It is illustrated with one hundred and ninety-eight wood-engravings, all of which are well executed and unusually clear, considering the reduced scale required by the small size of the volume.

As stated in the title, the work is intended mainly for students, and is probably meant to be used more as a convenient manual than as a substitute for the larger treatises, such as Quain's and Gray's.

The author's style is agreeable, and the typographical execution is such as to make a very attractive-looking volume.

### BOOKS, ETC., RECEIVED.

*Treatise on the Diseases of Women, for the Use of Students and Practitioners.* By Alexander J. C. Skene, M. D., Professor of Gynecology in the Long Island College Hospital, Brooklyn, N. Y.; formerly

Professor of Gynecology in the New York Post-graduate Medical School, etc. Second Edition, revised and enlarged. With 251 Engravings and 9 Chromolithographs. New York: D. Appleton & Co., 1892. Pp. xiv to 968.

How to feel the Pulse and what to feel in it. Practical Hints for Beginners. By William Ewart, M. D. Cantab., F. R. C. P., Physician to St. George's Hospital, etc. With Twelve Illustrations. New York: William Wood & Co., 1892. Pp. xv to 112.

On Contractions of the Fingers (Dupuytren's and Congenital Contractions) and on "Hammer-toe." Including Two Essays on Dupuytren's Contraction of the Fingers, and its Successful Treatment by Subcutaneous Divisions of the Palmar Fascia, and Immediate Extension. One Essay on Congenital Contraction of the Fingers and its Association with Hammer-toe; its Pathology and Treatment. One Essay on the Successful Treatment of Hammer-toe by the Subcutaneous Division of the Lateral Ligaments. And One Essay on the Obliteration of Depressed Cicatrices after Glandular Abscesses, or Exfoliation of Bone, by a Subcutaneous Operation. By William Adams, F. R. C. S. Eng. With Eight Plates and Thirty-one Wood Engravings. Second Edition. London: J. & A. Churchill, 1892. Pp. xx to 154.

Zeitschrift für orthopädische Chirurgie einschliesslich der Heilgymnastik und Massage. Unter Mitwirkung von Professor J. Wolff in Berlin, Dr. Beely in Berlin, Professor Dr. Lorenz in Wien, Privatdocent Dr. W. Schulthess in Zurich und Dr. Nebel in Frankfurt a M. Herausgegeben von Dr. Albert Hoffa, Privatdocenten der Chirurgie an der Universität Würzburg. I. Band. Mit 85 in den Texte gedruckten Abbildungen und 12 Tafeln. Stuttgart: Ferdinand Enke, 1892. Pp. iv to 487.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M. D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by Walter Chrystie, M. D., formerly Instructor in Physical Diagnosis in the University of Pennsylvania. Vol. III. Diseases of the Skin—Diseases of the Nervous System—Diseases of the Genito-urinary Apparatus—Diseases of the Eye—Diseases of the Ear. With Illustrations. Philadelphia: Lea Brothers & Co., 1892. Pp. 11-17 to 1352.

Materialism and Modern Physiology of the Nervous System. By William H. Thomson, M. D., LL. D., Professor of Materia Medica and of Diseases of the Nervous System in the University of New York. New York: G. P. Putnam's Sons, 1892. Pp. 112.

Psoriasis and the New Remedy—Gallacetophenone. By Juha W. Carpenter, M. D. [Reprinted from the *Lancet-Clinic*.]

Suppuration of the Middle Ear, complicated with Abscess of the Neck, with Report of a Case. By E. Oliver Belt, M. D., Washington, D. C. [Reprinted from the *Ophthalmic Record*.]

What is Homeopathy? A New Exposition of a Great Truth. By William H. Holcombe, M. D. Philadelphia: Boericke and Tafel.

The Successful Treatment of Chronic Diseases. A Plea for their more Methodical Management. By Simon Baruch, M. D. [Reprinted from the *Dietetic Gazette*.]

Expert Witnesses. By J. T. Eskridge, M. D., Denver, Colorado. [Reprinted from the *Denver Medical Times*.]

Charge to the Graduating Class. By J. M. Masters, M. D., Professor of Ophthalmology and Otolaryngology in the Tennessee Medical College. Delivered at the Third Annual Commencement. Knoxville, Tenn., March 17, 1892.

Opening of the Mastoid Process. By Dr. Harry Friedenwald, Baltimore.

The Pathology and Treatment of Tetanus; including a Series of Investigations in regard to the Micro-organism of the Disease and the Influence of Disinfectant Substances on the same. A Study from the Pathological Laboratory of the Jefferson Medical College. By D. Braden Kyle, M. D. [Reprinted from the *Therapeutic Gazette*.]

A Plea for the Medical Expert. By L. Harrison Mettler, A. M., M. D., of Chicago. [Reprinted from the *Journal of the American Medical Association*.]

Accidental Utero-vaginal Fistula following Hysterectomy; Cure by Kolpo-uretero-cystotomy, Gradual Preparatory Treatment, and Button-suture. By Nathan G. Bozeman, Ph. B., M. D. [Reprinted from the *New York Journal of Gynecology and Obstetrics*.]

Some Remarks on Pulmonary Tuberculosis, with Especial Reference to our Most Recent Knowledge on the Subject. By Louis F. Criado, M. D. [Reprinted from the *Brooklyn Medical Journal*.]

Results of Experiments with Inoculation for the Prevention of Hog Cholera. By Dr. D. E. Salmon, Chief of the Bureau of Animal Industry. [U. S. Department of Agriculture, *Farmers' Bulletin*, No. 2.]

Ueber intraoculäre Erkrankungen im Gefolge von Nasenkrankheiten. Von Dr. Ziem in Danzig. [Separatdruck aus der *Münchener medic. Wochenschrift*.]

Traitement de l'hystérie. Par le Dr. Paul Blocq. [Extrait de la *Gazette des hôpitaux*.]

Traitement de l'hypertrophie des amygdales. Par Dr. E. J. Moure. [Extrait des *Mémoires et bulletins de la Société de médecine et de chirurgie de Bordeaux*.]

Report relating to the Registration of Births, Marriages, and Deaths in the Province of Ontario, for the Year ending 31st December, 1890.

Acromegaly—Paralysis Agitans. By Simon Baruch, M. D. [Reprinted from *Illustrated Medicine and Surgery*.]

## Miscellany.

**The Commitment and Care of the Insane in the State of New York.**—The State Commission in Lunacy has issued the following circular:

By the statute no insane person can be admitted to an institution for the care and treatment of the insane except upon a medical certificate of lunacy, made jointly by two physicians, under a form prescribed by the State Commission in Lunacy. The form at present in use went into effect July 1, 1890, and commitments can now only be made under such form and upon blanks prepared and furnished by the State. These blanks can be obtained upon application to the State Commission in Lunacy, county clerks, superintendents of the poor, and superintendents of asylums or hospitals for the insane, both public and private. The medical certificate must be filled out strictly according to its terms in order to secure the commitment of a patient. There must be a final examination of the patient on the same day by both certifying physicians, although the final examination need not be conducted by each physician in the presence of the other. *The date of the final examination is the date of the certificate.* A patient can be admitted under such medical certificate at any time within ten days from its date—namely, the date of the final examination. While a patient may be admitted upon such certificate prior to its approval by a judge of a court of record, the patient can not be detained more than five days without such approval, and therefore it is advisable, in order to avoid delays and a re-examination when such approval is not made within the required time, to procure the approval prior to the admission of the patient. The approval must be made by a judge of a court of record, of the county or judicial district in which the patient resides. If, however, the patient has no fixed residence within the State, then the certificate may be approved by a judge of a court of record of the county or judicial district wherein such patient may be. A medical certificate prescribed by the commission is an absolute requisite to the commitment of a patient; a judge, however, may require other and additional evidence. He may summon witnesses or additional physicians, or may, in his discretion, call a jury in each case to determine the question of lunacy. Therefore, in order to avoid expense and delay, it is essential that great care should be taken in the preparation of such medical certificate. The statute provides that only such physicians as have been properly certified by a judge of a court of record, and only after a certified copy of their certificate of qualification has been filed in the office of the State Commission in Lunacy, can prepare such medical certificate. A medical certificate prepared by either one or both physicians whose certificate of qualification has not been filed in the office of the commission is void by statute and a re-examination of the patient must be had.

Section 2, chapter 446, Laws of 1874, provides that "It shall not

be lawful for any physician to certify to the insanity of any person for the purpose of securing his commitment to an asylum, unless said physician be of reputable character, a graduate of some incorporated medical college, a permanent resident of the State, and shall have been in the actual practice of his profession for at least three years. And such qualifications shall be certified to by a judge of any court of record."

Section 7 of chapter 283, Laws of 1889, as amended by chapter 273, Laws of 1890, provides that "One year after the date of the passage of this act (May 14, 1889) it shall not be lawful for any medical examiner in lunacy to make a certificate of insanity for the purpose of committing any person to custody unless a certified copy of his certificate has been so filed and its receipt in the office of the commission (State Commission in Lunacy), as above provided, has been acknowledged."

Public patients, except in the counties of New York and Kings, are required by the statute to be cared for in State hospitals situated within the hospital district in which they reside, the statute requiring that the State be divided into as many districts as there are State hospitals. A patient, however, who desires care and treatment in a State hospital situated beyond the hospital district in which he resides may be admitted to such hospital upon the following conditions:

*a.* When there is a vacancy. *b.* In the discretion of the president of the State Commission in Lunacy and the superintendent of the hospital to which the admission of the patient may be desired. *c.* That any expense of removal beyond the limits of the hospital district in such case must be borne by said insane person's guardians, relatives, or friends, as the case may be.

This statute is liberally construed, and in no instance has the consent of the president of the commission been refused or will such consent be refused in any proper case. When applications are made by mail or telegraph to the office of the commission, in Albany, such consent will be promptly given.

Public patients from the counties of New York and Kings may be admitted to any State hospital within the State, with the consent of the authorities of such hospital and the Commissioners of Charities and Corrections of either of said counties.

Private or pay patients may be admitted to any State hospital without reference to the hospital district in which they reside upon the following conditions:

*a.* That there is room. *b.* That the hospital authorities are willing to receive the patient. *c.* That no patient shall be permitted to pay a sum in excess of ten dollars per week.

The maximum sum of ten dollars per week to be charged for the care and treatment of a private or pay patient in a State hospital was agreed upon at a conference of the State Commission in Lunacy and the trustees and superintendents of State hospitals. This limit of price was fixed upon in order that the rights of the dependent insane for whom the State hospitals were established should not be encroached upon by patients who are able to pay a greater sum and who would require in return therefor a corresponding amount of room-space and other allowances which, in view of the constant demand for accommodations for the dependent insane, could not properly be accorded them. Each State hospital being established upon the principle of the greatest good to the greatest number, and recognizing no class distinctions, obviously no advantages, in the way of extra room-space, etc., can properly be given, and especially in view of the fact that adequate and competent private care and treatment, both allopathic and homoeopathic, can now readily be obtained for the non-dependent insane in private institutions, under the supervision of the State, for ten dollars per week and upward.

All private institutions for the care and treatment of the insane are required by statute to be licensed by the State Commission in Lunacy, and the commission is empowered to revoke any such license in its discretion, when proper cause exists therefor, and no insane person can be committed to any institution, retreat, home, or sanitarium which is not so licensed.

The following is a list of the licensed private institutions for the insane, with the name of the physician in charge, the location, and the minimum sum charged per week:

Institution.	Physician in charge.	Location.	Minimum rate per week.
Bloomington Asylum . . .	S. B. Lyon . . . . .	New York . . . . .	\$5 00
Providence Retreat . . . . .	Harry A. Wood . . . . .	Buffalo . . . . .	6 00
Marshall Infirmary . . . . .	J. D. Lomax . . . . .	Troy . . . . .	5 00
Long Island Home . . . . .	O. J. Wilsey . . . . .	Amityville . . . . .	10 00
Brigham Hall . . . . .	D. R. Burrell . . . . .	Canandaigua . . . . .	10 00
* St. Vincent's Retreat . . . . .	J. A. Underhill . . . . .	Harrison . . . . .	10 00
Sanford Hall . . . . .	J. W. Barstow . . . . .	Flushing . . . . .	25 00
* Dr. Wells's Sanitarium . . . . .	T. L. Wells . . . . .	Brooklyn . . . . .	10 00
Dr. Combes's Sanitarium . . . . .	R. C. F. Combes . . . . .	Woodhaven . . . . .	10 00
Dr. Choate's House . . . . .	G. C. S. Choate . . . . .	Pleasantville . . . . .	75 00
Dr. Parsons's House . . . . .	R. L. Parsons . . . . .	Sing Sing . . . . .	75 00
Falkirk . . . . .	J. F. Ferguson . . . . .	Central Valley . . . . .	20 00
Vernon House . . . . .	W. D. Granger . . . . .	Bronxville . . . . .	35 00
Breezehurst Terrace . . . . .	D. A. Harrison . . . . .	Whitestone . . . . .	20 00
Waldemere . . . . .	E. N. Carpenter . . . . .	Mamaroneck . . . . .	25 00
The Pines . . . . .	Fred Sefton . . . . .	Auburn . . . . .	20 00
Glennary Home . . . . .	J. T. Greenleaf . . . . .	Owego . . . . .	10 00
Dungartheil . . . . .	H. R. Stiles . . . . .	Lake George . . . . .	25 00

\* Receive female patients only.

Respectfully, T. E. MCGARR, Secretary.

**To Contributors and Correspondents.**—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

*Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.*

*All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.*

*Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.*

*Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.*

*All communications intended for the editor should be addressed to him in care of the publishers.*

*All communications relating to the business of the journal should be addressed to the publishers.*

REASONS WHY PHYSICIANS SHOULD  
SUBSCRIBE FOR THE

New York Medical Journal,

EDITED BY FRANK P. FOSTER, M. D.,

Published by D. APPLETON & CO., New York.

- 
- B**ECAUSE: It is the *LEADING JOURNAL* of America and contains more reading-matter than any other journal of its class.
- B**ECAUSE: It is the exponent of the most advanced scientific medical thought.
- B**ECAUSE: Its contributors are among the most learned medical men of this country.
- B**ECAUSE: Its "Original Articles" are the results of scientific observation and research, and are of infinite practical value to the general practitioner.
- B**ECAUSE: The "Reports on the Progress of Medicine," which are published from time to time, contain the most recent discoveries in the various departments of medicine, and are written by practitioners especially qualified for the purpose.
- B**ECAUSE: The column devoted in each number to "Therapeutical Notes" contains a *résumé* of the practical application of the most recent therapeutic novelties.
- B**ECAUSE: The Society Proceedings, of which each number contains one or more, are reports of the practical experience of prominent physicians who thus give to the profession the results of certain modes of treatment in given cases.
- B**ECAUSE: The Editorial Columns are controlled only by the desire to promote the welfare, honor, and advancement of the science of medicine, as viewed from a standpoint looking to the best interests of the profession.
- B**ECAUSE: Nothing is admitted to its columns that has not some bearing on medicine, or is not possessed of some practical value.
- B**ECAUSE: It is published solely in the interests of medicine, and for the upholding of the elevated position occupied by the profession of America.

---

The volumes begin with January and July of each year. Subscriptions can be arranged to begin with the volume.

*Subscription Price, \$5.00 per Annum.*

The Popular Science Monthly and the New York Medical Journal to the same address, \$9.00 per Annum (full price, \$10.00).
